Major histocompatibility complex class I and II genes are highly polymorphic in the regions that encode the peptide-binding groove. These polymorphisms help to ensure survival of the species by increasing the variety of peptides that can be presented to T cells. Thus, MHC polymorphisms decrease the chance of encountering pathogens that induce poor immune responses within a population and therefore could lead to the demise of the species.[16] However, it is also these polymorphisms that predispose to allograft rejection, because the antigen presenting structures of one individual are regarded as foreign by another nonidentical individual.

Originally, polymorphisms were defined by HLA serologic (antibody) typing using sera from multiparous women or persons who had received blood transfusions. The development of molecular biology techniques (polymerase chain reaction [PCR] sequencing) has allowed the analysis of the HLA allelic sequence diversity at the DNA level. By DNA typing, many more polymorphisms (alleles) have been identified: currently 2188 for HLA-A, 2862 for HLA-B, 1746 for HLA-C, and 1393 for HLA-DR, with an increasing number of sequences added each year. The most currently updated source for HLA alleles can be identified at the website www.ebi.ac.uk/imgt/hla. Although PCR techniques allow for rapid DNA sequence-based typing of human populations, serologic methods are still often used for identifying HLA antigens in kidney transplantation.

Human Leukocyte Antigen Inheritance

Human leukocyte antigen genes are inherited in a Mendelian co-dominant fashion, meaning that a copy of each HLA gene (i.e., one haplotype) is inherited from each parent and expressed as antigens. HLA typing identifies the specific alleles carried by a person. The term *HLA matching* means assigning a donor kidney to a recipient with as few mismatches as possible. In kidney transplantation, efforts are made to match HLA-A, HLA-B, and HLA-DR genes and proteins. It can be predicted that siblings from the same set of parents will have a 25% chance of having zero mismatches, a 50% chance of one haplotype mismatch, and a 25% chance of two haplotype mismatches (Fig. 100-4).

Non–Major Histocompatibility Complex Antigens

Minor histocompatibility antigens are normal proteins that are themselves polymorphic within a given species. Even when a transplant donor and recipient are identical with regard to MHC genes, amino acid differences in these minor proteins can lead to rejection. Minor antigens are encoded by a large number of chromosomes and are presented only as peptides in the context of recipient MHC (indirect allorecognition). Minor antigens are responsible for the need for immunosuppression after donation between HLA matched nonidentical twin siblings. The prototypic minor histocompatibility antigen, the male or H-Y antigen, is derived from a group of proteins encoded on the Y chromosome. Alloresponses to this antigen are responsible for rejection of male mouse skin grafts by otherwise identical female recipients and may explain observations of reduced long-term graft survival in human male-to-female donations.

Major histocompatibility complex I-related chain A (MICA) antigens are surface glycoproteins with functions related to innate immunity. Exposure to allogeneic MICA during transplantation can elicit antibody formation.[17] ABO blood group glycolipids expressed on endothelial and red blood cells are other notable non-MHC antigens. Finally, immune responses to autoantigens have been associated with allograft damage.[18]

T CELL ACTIVATION

T cells are required for rejection, because animals experimentally deprived of T cells through mutation or genetic manipulation are unable to reject allografts. Alloreactive T cells can be found in the naive and memory T cell populations, but both require recognition of nonself MHC molecules to become activated. Reactions mediated

by naive T cells take longer to develop than those mediated by memory T cells, which can be generated more quickly and with higher numbers of cells (secondary response). During allograft rejection, both populations are activated simultaneously.

T Cell Receptor

Each T cell bears about 30,000 identical antigen-receptor molecules. Each receptor consists of two different polypeptide chains, termed the TCR α and β chains, which are linked by a disulfide bond. The genes encoding the TCR chains are members of the immunoglobulin (Ig) supergene family, which are found on B, T, and NK cells. The α:β heterodimers are very similar in structure to the Fab fragment of an Ig molecule and account for antigen recognition by most T cells (Fig. 100-5). In contrast to the Ig receptors of B cells, TCRs do not recognize antigen in its native state, but instead recognize a composite ligand of a peptide bound to an MHC molecule. A minority of T cells bears an alternative, but structurally similar, receptor composed of a different polypeptide heterodimer (γ:δ).

CD4 and CD8 Coreceptors

T cells fall into two major classes with different effector functions, distinguished by the expression of the cell-surface proteins CD4 and CD8 (see Fig. 100-5). Both CD4 and CD8 have a cytoplasmic tail that can associate with signaling proteins important in T cell activation. CD4 and CD8 binding to MHC are required to make an effective response. Thus, these molecules are called *coreceptors.*

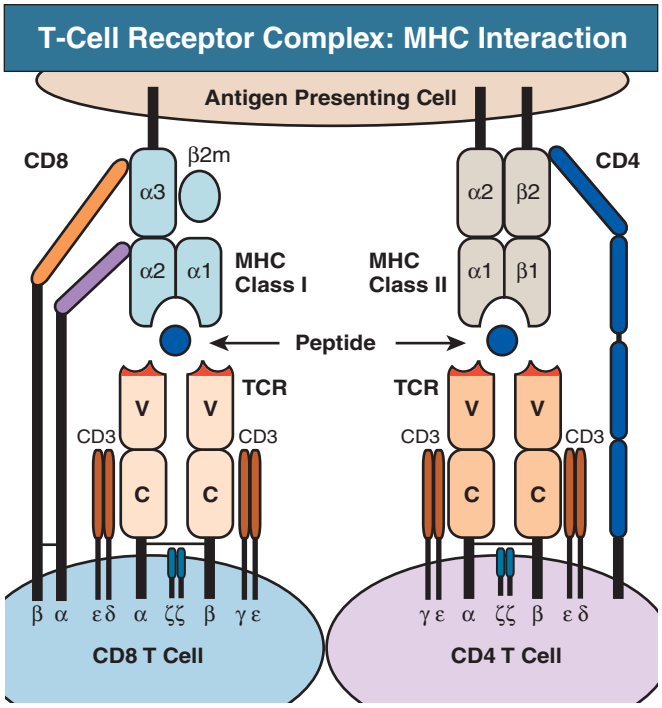

Figure 100-5 T cell receptor complex: major histocompatibility complex (MHC) interaction. Each T cell receptor *(TCR)* consists of an α and a β chain linked by a disulfide bond. The α:β heterodimers are similar in structure to the Fab fragment of an immunoglobulin (Ig) molecules (see Fig. 100-7), including variable *(V)* and constant *(C)* regions. Diversity in the T cell repertoire is encoded in the V domains of the α and β chains in three complementarity determining regions (CDRs) that form the antigen binding site at the end of the TCR *(highlighted in red).* CD8 is a disulfide-linked α:β heterodimer or α:α homodimer, with each chain containing a single Ig-like domain linked to the membrane by a polypeptide chain. CD8 binds to the conserved region of the α3 domain of the class I MHC molecule on antigen-presenting cells (APCs), but also interacts with the class I MHC α2 domain, probably through the α chain. CD4 is composed of four Ig-like domains and binds to a conserved site on the β2 domain of the class II MHC molecule on APCs. Triggering of the TCR by antigen initiates a signaling cascade started by the signaling complex made up of CD3 γ, ε, and δ chains, as well as the ζ chain homodimer. *β2m,* β_2-microglobulin.

T Cell Receptor Engagement of Antigen: Signal 1

The TCR α:β heterodimer recognizes and binds its peptide-MHC ligand[19] but cannot signal to the cell that antigen has bound. In the functional receptor complex, α:β heterodimers are associated with a complex of four other signaling chains (two ε, one δ, one γ) collectively called *CD3* (see Fig. 100-5). Engagement of the TCR by MHC, along with the other required receptor engagements, initiates the signaling process from the CD3 complex, leading to cell proliferation and differentiation.[20]

T Cell Costimulation: Signal 2

Binding of the TCR-CD3 complex to the peptide-MHC complex on APCs delivers a signal that can induce the clonal expansion of naive T cells only when the appropriate costimulatory signal is delivered (Signal 2). CD8 T cells require a stronger costimulatory signal, and their clonal expansion is aided by CD4 T cells interacting with the same APC (i.e., T helper function). Costimulation is likely a checkpoint developed by the immune system to prevent the activation of self-reactive T cells that escaped negative selection in the thymus. Antigen binding to the TCR in the absence of costimulation not only fails to activate the T cell but leads to a state called *anergy,* in which T cells become refractory to subsequent activation, or even undergo apoptosis (programmed cell death). Thus, costimulation removes this inhibition and determines whether a T cell will proceed with clonal expansion and the development of effector functions. It is now clear that costimulatory molecules can provide positive or negative signals to T cells (Fig. 100-6). It is the integration of both positive and negative costimulatory signals during and after initial T cell activation, dictated by their temporal and spatial expression patterns, that ultimately determines the fate and functional status of the T cell response.[21]

T Cell Clonal Expansion and Differentiation

In most instances the number of T cells that react to a given antigen is quite small. Therefore, effective immune responses generally require clonal expansion and differentiation of T cells. These processes are largely driven by cytokines, including IL-2, which acts on the T cell in an autocrine fashion or by paracrine secretion to neighboring T cells. Activated T cells produce the alpha subunit (CD25) of the IL-2 receptor (IL-2R), enabling a fully functional signaling receptor composed of α, β, and γ subunits that can bind IL-2 with high affinity, which in turn initiates another pathway mediated in part through a protein called *mammalian target of rapamycin* (mTOR). A number of new proteins are then translated, allowing the cell to progress from the G1 phase to the S phase of the cell cycle, resulting in proliferation. The list of cytokines involved in this and later processes is large and continues to grow. Table 100-1 lists selected cytokines involved in allograft rejection, their sources, and their effects.

CD4 and CD8 T cells have different roles during immune responses. CD4 T cells are both effectors and regulators and are notable for heavy cytokine secretion. After prolonged stimulation, CD4 T cells sometimes tend to express groups of several cytokines, probably depending on the local environment, the nature of the antigen, and the type and activation status of the APCs. The so-called

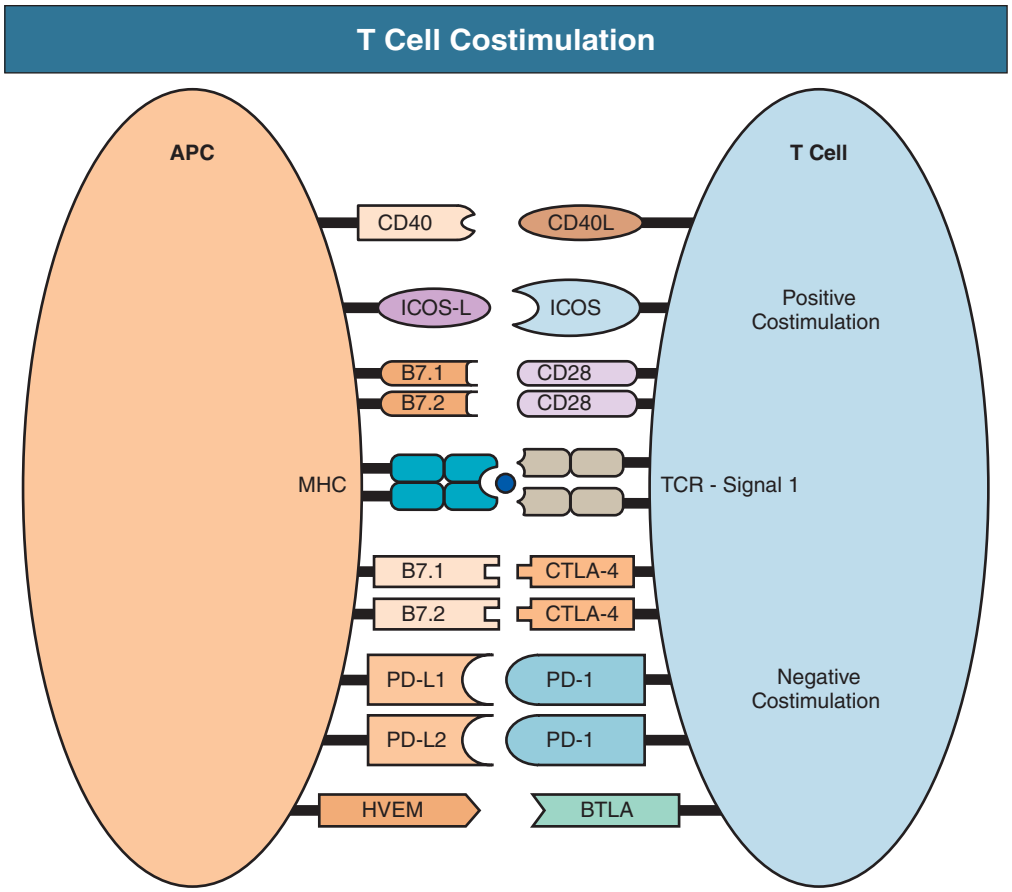

Figure 100-6 T cell costimulation. Binding of the T cell receptor *(TCR)*–CD3 complex to the peptide-MHC complex on an antigen-presenting cell *(APC)* delivers a signal that can induce the clonal expansion of naive T cells only when the appropriate costimulatory signal is delivered (Signal 2). CD28 and its ligands, B7.1 (CD80) and B7.2 (CD86), are the best-characterized costimulatory molecules and are members of the immunoglobulin (Ig) superfamily. Ligation of CD28 by B7 molecules is required for clonal expansion of naive CD4 T helper cells. Once activated, T cells express increased levels of CTLA-4 (CD152). CTLA-4 has an affinity 10 to 20 times greater than CD28 for B7 molecules and thus binds most or all of the B7 molecules, effectively shutting down the proliferative phase of the response. B and T lymphocyte attenuator (BTLA) and programmed death–1 (PD-1) are two other costimulatory molecules of the Ig superfamily that when engaged by their ligands (herpes virus entry mediator [HVEM] and PD-L1/PD-L2, respectively) provide inhibitory signals to T cells. Activated T cells express a number of proteins that contribute to sustaining or modifying the costimulatory signal to drive clonal expansion and differentiation. The inducible costimulatory molecule (ICOS) is a CD28 homologue, but unlike CD28 is not constitutively expressed on naive T cells. Rather, ICOS is induced only after T cell activation. Engagement of ICOS by B7H enhances T cell proliferation, cytokine production, and survival. Costimulatory molecules of the TNF and TNF-R superfamily include CD40 ligand (CD40L, CD154) on T cells and its receptor CD40 on APCs, such as B cells, dendritic cells (DCs), macrophages, and endothelial cells. Binding of CD40 by CD40L, which is upregulated by CD28 signaling, transmits activating signals to the T cell but also activates the APCs to secrete proinflammatory molecules and to express B7 molecules, thus stimulating further T cell proliferation.

Th1 (T helper 1) clones produce IL-2, IFN-γ, and lymphotoxin, whereas Th2 clones produce IL-4, IL-5, and IL-10. As the effects of these cytokines became known, it was apparent that the subdivision of production correlated with a categorization of function. Th1-derived cytokines are growth and maturation factors for CTLs (especially IL-2) and macrophages (particularly IFN-γ), whereas Th2-derived cytokines act similarly on B cells. Th2 cells also mediate B cell class switching to complement IgG fixing antibodies. Rejecting allografts typically express high levels of mRNA for both subsets of cytokines and cannot be considered a pure Th1 response. T helper 17 (Th17) cells are a subset of T helper cells stimulated by TGF-β and a number of other cytokines that are distinct from Th1 and Th2[22] clones and produce IL-17, IL-21, and IL-22.[23] Th17 cells are thought to play a key role in autoimmune disease, and their role in transplantation is currently under intense investigation.[24]

Memory Cells

Although there is limited knowledge of how memory T cells are generated or maintained, these cells are an important component of the immune response to infectious pathogens. In clinical transplantation, however, previous sensitization to alloantigen with formation of memory cells is associated with increased risk for acute rejection and premature graft failure. Memory responses to alloantigen frequently occur at the time of blood transfusion, pregnancy, and transplantation. However, alloantigen memory responses can develop as a result of antigen cross-reactivity during response to infection (heterologous immunity), but also by normal proliferation in response to lymphopenia induced by leukocyte-depleting agents in transplant recipients.

The principle of immunologic memory is that the immune response to a previously encountered antigen is swifter and more effective than the response to a new antigen. Memory cells seem to be more easily activated than naive T cells, with a lower requirement for costimulation, and in addition produce more cytokines. Furthermore, there is an increase in antigen-specific T cell frequency after exposure to a given antigen. Finally, exposure to antigen leads to a refinement of the antibody repertoire, resulting in a more effective memory response. Effector memory T cells are specialized for quickly entering inflamed tissues, because they can rapidly mature

Cytokines Involved in Allograft Rejection		
Cytokine	**Source**	**Biologic Activity**
IL-1	Macrophages, DCs, ECs, NK cells	Proinflammatory, adhesion molecule expression on ECs, NK cell function
IL-2	Activated T cells	T cell proliferation, CTL and NK cell function, Treg maintenance, Ig production by B cells, AICD of activated T cells
IL-4	Activated T cells	Activated T and B cell proliferation, Th2 differentiation, allergic responses, MHC II upregulation on B cells
IL-6	T cells, macrophages, ECs	Proinflammatory and anti-inflammatory, acute-phase responses
IL-10	T cells, macrophages, DCs	Anti-inflammatory, suppression of APC function, NK cell inhibition
IL-12	Macrophages, DCs	Proinflammatory, Th1 differentiation, NK cell and CTL activity, IFN-γ and TNF-α production by NK and T cells
IL-15	Epithelial cells, stromal cells, macrophages	NK cell proliferation, T cell proliferation, memory T cell survival
IL-17	T cells	Proinflammatory and allergic responses, Th17 function, cytokine production from many cell types
IFN-γ	Activated Th1 cells, CTLs, DCs, NK cells	MHC expression by EC, macrophage function, Th1 differentiation, Th2 suppression, adhesion and binding of T cells to ECs, NK cell activity
TGF-β	T and B cells, macrophages, platelets	Anti-inflammatory, wound healing, fibrosis
TNF-α	Macrophages, T and B cells, ECs, NK cells	Proinflammatory, acute phase responses, cytotoxicity

Table 100-1 Cytokines involved in allograft rejection. *AICD,* Activation-induced cell death; *CTLs,* cytotoxic T lymphocytes; *DCs,* dendritic cells; *ECs,* endothelial cells; *IFN-γ,* interferon-γ; *Ig,* immunoglobulin; *IL,* interleukin; *MHC,* major histocompatibility complex; *NK,* natural killer; *TGF-β,* transforming growth factor beta; *Th,* T helper (cell); *TNF-α,* tumor necrosis factor α; *Treg,* regulatory T cell.

into effector T cells and secrete larger amounts of cytokines after restimulation. Central memory T cells likely remain in the SLOs and do not produce as much cytokine.[25] Memory cells are believed to persist after an initial immune response through expression of the antiapoptotic genes *Bcl-2* and *Bcl-xL*, which are induced primarily by IL-2 and CD28 stimulation, although IL-15 may also provide survival signals. Long-term memory cell survival is likely a function of periodic interactions with self-MHC–peptide complexes on APCs (i.e., homeostatic proliferation).

EFFECTOR FUNCTIONS

Once activated and expanded, T cells exert effector functions that result in destruction of graft tissue. Although T cells are essential for acute organ allograft rejection, the precise mechanisms by which they mediate graft injury are uncertain. CD4 T helper cells may release numerous cytokines that affect the alloimmune response. For example, they may promote delayed-type hypersensitivity (DTH) responses that involve stimulating production of nitric oxide, reactive oxygen species, and TNF-α by macrophages. T cell cytokines may also act directly on parenchymal cells or indirectly through effects on the endothelium and vascular supply. TNF-α and TNF-β exert local cytotoxic effects on receptors on the graft, including endothelial cells (TNF-R1) and tubular cells (TNF-R2). IFN-γ, the prototypical Th1 cytokine, is released by both CD4 and CD8 T cells during rejection. IFN-γ induces MHC class II expression on endothelium and MHC class I expression on vascular endothelial cells, epithelial cells, and parenchymal cells in the graft. The precise role of class II expression by donor cells in the graft remains controversial because mouse kidney grafts lacking class II are rejected more vigorously. Although IFN-γ is strongly associated with rejection, it probably has other signaling roles that actually help to stabilize the graft. As cytokine production by CD8 T cells is generally lower than that of CD4 T cells, production of cytokines such as IL-2 by CD4 T cells provides help for the generation of CTLs from their CD8 T cell precursors. CD4 T cells may themselves become cytolytic T cells, by mechanisms similar to those used by CD8 CTLs (described later). CD4 T cells also provide help to B cells to enhance their production of alloantibodies. Finally, regulatory T cells (Tregs) may have important roles in suppressing immune responses and maintaining tolerance.

Cytotoxic T Lymphocyte Differentiation and Function

With rare exceptions, virtually all CTLs are MHC class I–restricted CD8 T cells. Activated CTLs possess two mechanisms to kill target cells that require cell-to-cell contact.[26] The first mechanism is by the release of specialized lytic granules. Perforin and granzyme B are two proteins found in granules of most CTLs and NK cells. Perforin, like complement components, has the ability to induce transmembrane pores. The granzyme B–perforin complex enters the cell through the mannose 6-phosphate receptor, and, after internalization, perforin allows granzyme B to enter the cell through the vesicle surface to induce programmed cell death through apoptosis.[27] A third cytotoxic protein, granulysin, is also able to induce apoptosis in target cells. The second mechanism is by Fas/Fas ligand (FasL) interactions. Fas (CD95) is a member of the TNF-R family and is the surface mediator of a pathway that, when activated by FasL on activated CTLs, induces the target cell to undergo apoptosis. Both pathways induce apoptosis through activation of the caspase cascade in target cells. As previously alluded to, CD8 CTLs also release several cytokines that exert direct cytotoxic effects, including IFN-γ, TNF-α and TNF-β.[28] Effector CD4 T cells that can mediate class II-restricted cytotoxicity to minor antigens have also been detected.

Macrophage Activation

The activated macrophage is an important mediator of DTH responses, which leads to localized tissue destruction. Resting macrophages must be activated to exert full inflammatory and cytopathic effects. Th1 cells provide help for this activation by interaction of CD40L with CD40 on the macrophage and by production of IFN-γ, which sensitizes the macrophage to respond to IFN-γ. It is possible

that T cell membrane–associated TNF-α and TNF-β can substitute for CD40L. CD8 T cells also produce IFN-γ and can activate macrophages. Production of TNF-α, oxygen radicals, and nitric oxide by activated macrophages are important for their cytopathic effects. Activated macrophages can also produce IL-12, which directs the differentiation of activated naive CD4 T cells into Th1 effector cells. Macrophage activation is inhibited by cytokines such as transforming growth factor β (TGF-β) and IL-10, many of which are produced by Th2 cells.

Humoral Immune Response

The extracellular spaces of the body are protected by the humoral immune response, in which antibodies produced by B cells cause the destruction of extracellular microorganisms and prevent the spread of intracellular infections. Membrane-bound Ig on the B cell surface serves as the antigen receptor and is known as the *B cell receptor* (Fig. 100-7). It is associated with antigen-nonspecific signaling molecules Igα and Igβ. Ig of the same specificity is then secreted as antibody by terminally differentiated B cells (i.e., plasma cells). B cells develop in the bone marrow and undergo sequential rearrangement of Ig gene segments to generate a diverse repertoire of antigen receptors that can interact with antigen in their environment. In a process similar to that for developing T cells in the thymus, immature B cells that are strongly self-reactive at this stage are inactivated by negative selection. In contrast to T cells, new B cells are continually produced in adulthood.

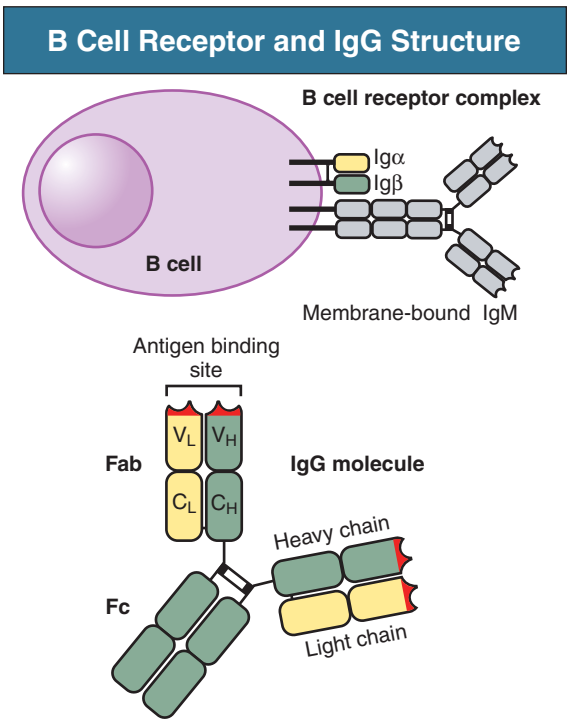

Figure 100-7 B cell receptor and IgG structure. B cell surface membrane–bound IgM associated with antigen-nonspecific signaling molecules Igα and Igβ forms the B cell receptor complex. The IgG molecule is made up of four polypeptide chains, comprising two identical light *(L)* chains *(yellow)* and two identical heavy *(H)* chains *(green)*. Each of the four chains has a variable *(V)* region at its amino terminus (*Fab* portion), which contributes to the antigen binding site, and a constant *(C)* region (*Fc* portion), which determines the isotype. The V domains contain hypervariable regions that determine antigen specificity called *complementarity-determining regions (highlighted in red)*.

B cell activation requires binding of antigen to the BCR. Although some polysaccharides and polymeric proteins can activate B cells directly, antibody responses to most proteins require both binding of the antigen to the BCR and interaction of the B cell with antigen-specific helper T cells. Helper T cells recognize peptide fragments derived from the antigen that are internalized and presented as peptide–MHC class II complexes on the B cell surface. Helper T cells stimulate B cells through the binding of CD40L with CD40 on B cells, through interaction of other TNF–TNF-R family ligands, as well as the directed release of cytokines. Although these helper T cells are generally of the Th2 subset, Th1 cells can also assist with B cell activation. Activated B cells also provide signals to T cells via B7 family molecules that promote their continued activation.

Secretion of antibodies, which bind pathogens or their toxic products, is the main effector function of B cells in adaptive immunity. The antibody molecule has two separate functions: One is to bind specifically to molecules from the pathogen that elicited the immune response, and the other is to recruit other cells and molecules to destroy the pathogen bound by the antibody. The five major classes of antibodies are IgM, IgD, IgG, IgA, and IgE. IgG is by far the most abundant Ig and has several subclasses (IgG1, IgG2, IgG3, and IgG4). The IgG molecule is made up of four polypeptide chains, comprising two identical light (L) chains of 25 kd and two identical heavy (H) chains of 50 kd that form a flexible Y-shaped structure (see Fig. 100-7). Each of the four chains has a variable (V) region at its amino terminus (Fab portion), which contributes to the antigen binding site, and a constant (C) region (Fc portion), which determines the isotype. The V regions of a given antibody contain hypervariable segments that determine antigen specificity by forming a surface complementary to the antigen and are referred to as *complementarity-determining regions* (CDRs).

After appropriate activation and help from T cells, previously naive B cells undergo vigorous proliferation, secrete IgM, and then undergo differentiation into memory B cells or antibody-secreting plasma cells. During this process the antibody isotype can change (to IgA, IgG, or IgE) in response to cytokines released by helper T cells, and the antigen-binding properties of the antibody can change by somatic hypermutation of the V region genes. T helper cells selectively activate higher-affinity mutants, resulting in high-affinity plasma cells and memory B cells. Antibodies can function in several different ways once bound to their target antigen. These mechanisms include fixation of complement, opsonization for phagocytosis by Fc receptor (FcR)–positive cells (including B lymphocytes, NK cells, macrophages, and neutrophils), opsonization for cell lysis by cells capable of antibody-dependent cellular cytotoxicity (NK cells, macrophages, neutrophils, and eosinophils), and induction of eosinophil degranulation.

Natural Killer Lymphocytes

Natural killer cells are a subset of peripheral lymphocytes, which share certain developmental and functional features with the more numerous CD8 T lymphocytes.[29] Unlike T or B cells, NK cells do not possess a clonotypically distributed, antigen-specific cell surface receptor that is generated by gene recombination. Instead, NK cells use an array of receptors that recognize the loss of HLA class I molecules on susceptible targets. Peripheral NK cells are mature, do not require costimulation and differentiation as with T cells, and immediately release cytotoxic granules and inflammatory cytokines such as TNF-α and IFN-γ on detection of relevant targets. Given the strong cytolytic function and potential for autoreactivity, NK cell activity is tightly regulated. Mechanisms of activation include cytokines, binding of antibody to Fc receptors, and binding of ligands to

activating and inhibitory receptors. NKG2D is an activating receptor expressed on all NK cells and NK T lymphocytes.[4] The presence of NKG2D ligands, including MHC class I–related antigen, has been reported on human transplant samples undergoing acute allograft rejection and acute tubular necrosis. Thus, NKG2D ligands in the graft may stimulate a cytolytic cellular immune response after transplantation by interacting with cells bearing NKG2D, including NK cells. The role NK cells play during rejection is still being investigated.[30]

Termination of the Immune Response

To avoid massive continued expansion of the lymphoid pool, it is important to have mechanisms in place to terminate the immune response. Once the source of antigen is destroyed, there is no longer an inciting stimulus to induce further activation and proliferation of lymphocytes. However, preexisting effector cells can cause antigen-specific tissue damage and must be deactivated. Several mechanisms accomplish this task. Once terminally mature, DCs switch cytokine production from IL-12 to IL-10, favoring the generation of regulatory mechanisms that suppress the function of effector T cells. As mentioned previously, induction of CTLA4 after T cell activation provides regulatory feedback to provide inhibitory signals to T cells that induce anergy. In the absence of continued cytokine production, T cells lack the necessary growth factors and undergo passive cell death. Finally, activated T cells undergo activation-induced cell death (AICD) by the expression of Fas and FasL on their surface. Engagement of Fas by its ligand triggers a death signal, leading to apoptosis of the cell. Although IL-2 is important for the clonal expansion of T cells, it is also essential for AICD. Finally, Tregs are important in maintaining self-tolerance after removal of effector T cells.[31]

ALLOGRAFT REJECTION

Allograft rejection is defined as tissue injury produced by the effector mechanisms of the alloimmune response, leading to deterioration of graft function.[32] There are two types of rejection: T cell–mediated rejection (TCMR) and antibody-mediated rejection (AMR). Both types of rejection can be early or late, fulminant or indolent, isolated or concomitant, and can share pathologic features on biopsy.[33] For the purposes of this chapter, the two types are described separately.

Recruitment of Cells into the Interstitium of Kidney Allografts

Allograft rejection is caused by several cellular elements of the immune system, including T cells, macrophages, B cells, plasma cells, eosinophils, and neutrophils. Although there are a variety of target cells in the graft, endothelial and tubular cells are particularly affected by these mediators. T cells serve as the main effectors and regulators of the alloimmune response, whereas macrophages serve as possible effectors but also aid in the removal of apoptotic cells. B cells and plasma cells serve in the production of alloantibodies, and neutrophils likely cause significant damage, particularly during AMR.

A three-step model has been proposed to explain the entry of cellular infiltrates into the allograft: tethering, adhesion, and transmigration. Table 100-2 lists several of the proteins involved in this process. The endothelium of postcapillary venules in the graft serves as the entry point of recipient leukocytes from the bloodstream. Selectins are constitutive and inducible lectin-like molecules on the endothelium that cause leukocytes to roll along the vessel wall, a process called *tethering.* Leukocytes slowed down by selectins come into more prolonged contact with the endothelium. As a result, leukocytes are stimulated by chemokines, a group of small proinflammatory molecules produced by inflamed tissue, which are fundamentally important in attraction of cells into an inflammatory infiltrate. Once secreted, chemokines bind locally to cell-surface proteoglycans on endothelial cells, allowing them to activate leukocytes as they roll by. As chemokines bind to receptors on leukocytes, they activate the adhesion function of integrins.

Integrins are αβ heterodimers formed by noncovalent association. The best characterized integrin, leukocyte function-associated antigen 1 (LFA-1), is expressed on most leukocytes. The ligands for LFA-1, including intercellular adhesion molecule 1 (ICAM-1), ICAM-2, and ICAM-3 (Ig superfamily gene members), are expressed weakly on resting endothelium but are induced by activation with cytokines, such as IL-1 and TNF-α. Likewise, activation of leukocytes by chemokines triggers the transition of their surface LFA-1 to a high-affinity state for ICAM, resulting in tight adhesion of the leukocyte to the endothelium. This adhesion contributes to antigen recognition, and through a process called *haptotaxis,* leukocytes are induced to move along the vessel wall by an adhesion gradient.

Transmigration is the final step in the process of cellular entry into the allograft. Rapidly after integrin engagement of their ligands, leukocytes flatten and then undergo diapedesis through gaps between

Proteins Involved in the Recruitment of Leukocytes into Allografts

Protein Type	Name	Ligand	Function
Selectins	CD62L (L-selectin) CD62L (P-selectin) CD62L (E-selectin)	Sialylated glycoproteins	Initial rolling of leukocytes on endothelium
Chemokines	MCP-1/CCL2	CCR2	Recruitment of monocytes, immature DCs, T cells, and NK cells
	MIP-1α/CCL3	CCR1	Recruitment of monocytes, immature DCs, T cells, and neutrophils
	RANTES/CCL5	CCR1, CCR4, CCR5	Recruitment of monocytes, DCs, T cells, NK cells, and neutrophils
	IL-8/CXCL8	CXCR1, CXCR2	Recruitment of neutrophils
	MIG/CXCL9	CXCR3	Recruitment of activated memory T cells
	IP-10/CXCl10	CXCR3	Recruitment of activated memory T cells
	Lymphotactin/XCL1	XCR1	Recruitment of T cells
Immunoglobulin superfamily	CD54/ICAM-1	LFA-1	Tight adhesion of leukocytes to endothelium
	CD102/ICAM-2	LFA-1	Tight adhesion of leukocytes to endothelium (not as strong as ICAM-1)
	CD50/ICAM-3		
	CD106/VCAM-1	VLA-4	Rolling and tight adhesion of leukocytes to endothelium
	CD31/PECAM-1	CD31	Extravasation of leukocytes across endothelium

Table 100-2 Proteins involved in the recruitment of leukocytes into allografts. *DCs,* Dendritic cells; *ICAM,* intercellular adhesion molecule; *LFA-1,* leukocyte function-associated antigen 1; *NK,* natural killer; *PECAM,* platelet endothelial cell adhesion molecule; *VCAM,* vascular cell adhesion molecule; *VLA-4,* very late antigen-4.

endothelial cells. Leukocyte secretion of proteases degrades the basement membrane, allowing their escape from the vessel. Once in the interstitium, secretion of metalloproteinases allows leukocytes to digest extracellular matrix to move through the tissue on a chemokine gradient by a process called *chemotaxis.* Once confronted with foreign antigen in the allograft, previously activated T cells are capable of releasing proinflammatory cytokines (helper T cells) or directly killing foreign cells (cytotoxic T cells). Recent work in mouse models of renal allograft rejection indicates that allorecognition by T cells occurs in perivascular sites by day one after allotransplantation, whereas alloimmune parenchymal damage begins at day three, coinciding with the emergence of T cell and monocyte, macrophage, and DC (MMDC) infiltrates. Finally, tubulitis and arteritis develop by day 7.[30]

Acute T Cell–Mediated Rejection

Tubulitis, invasion of the tubular epithelium by infiltrating T cells and myeloid cells of the MMDC series, is a characteristic feature of acute TCMR (Fig. 100-8). In fact, deterioration of renal function during TCMR correlates with tubulitis and arterial inflammation (endothelialitis), which is much less common. Although it is generally agreed that T cells orchestrate the process that results in damage to the allograft, the precise mechanisms are not clear. As described earlier, CTLs can kill target cells by release of cytotoxic molecules (perforin, granzyme B, and granulysin) or by engagement of Fas on target cells by FasL, with both mechanisms resulting in apoptotic death of the target cell. Human gene expression studies show an increase in mRNA for CTL-associated transcripts, including granzyme B, perforin, and FasL, as well as T-bet, a master transcription factor for effector Th1 lymphocytes, during rejection episodes. Moreover, lymphocytes expressing mRNA and perforin protein are closely associated with tubular epithelial cells. Some studies suggest that tubulitis may involve a specific subset of CTLs expressing the integrin CD103, which binds to its ligand E-cadherin on epithelial cells, resulting in retention of T cells in the tubules.

Proof of mechanisms in organ transplantation, however, relies on *in vivo* models in animals. Although class I MHC mismatched heart allografts show prolonged survival in perforin knockout mice, most available evidence with perforin/granzyme, Fas/FasL, and CD103 knockouts indicates that any one of these individual cytolytic pathways is dispensable, because acute rejection still occurs with these deficiencies in fully mismatched combinations.[34] These studies argue against cytotoxicity as a primary mechanism to explain graft epithelial cell deterioration. Likewise, CD103–E-cadherin interactions may not be responsible for creating the lesions of tubulitis, but rather may reflect damaged cells that lose the ability to exclude inflammatory cells. Thus, tubulitis may not be the cause of tubular cell deterioration but instead a sign that is has already occurred.

T cells may mediate rejection instead through the secretion of cytokines, either through direct effects of soluble products or through the ability to activate macrophages to organize a DTH response. DTH responses involve the release of reactive oxygen species, proteolytic enzymes, eicosanoids, and other products. These products may act directly on tubular epithelium and interstitial matrix or indirectly via effects on endothelium and the vascular supply.

Endarteritis is detected in a minority of biopsy specimens taken for acute TCMR and often responds only to anti–T cell therapies, arguing for a pathogenic role for T cells. Endarteritis is not always associated with interstitial inflammation, arguing for a T cell pathway distinct from that of tubulointerstitial rejection. Glomerulitis is an occasional feature of acute TCMR, and cells are typically a mixture of T cells and macrophages. Why the glomerulus becomes the target in only a minority of patients is not currently known. FOXP3+ CD4 Tregs are concentrated in tubules during rejection, although their role during TCMR continues to be debated.

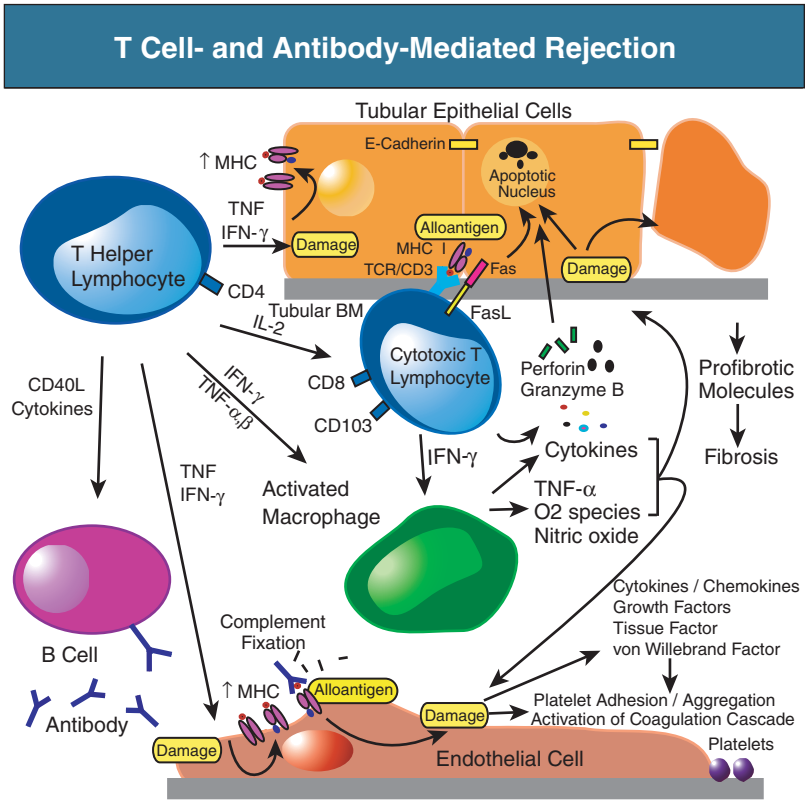

Figure 100-8 T cell– and antibody-mediated rejection. CD4 T cells induce epithelial and endothelial cell damage directly by secretion of cytokines but also indirectly by activation of cytotoxic T lymphocytes (CTLs) and macrophages. CTLs may cause apoptosis by releasing cytolytic granules containing granzymes and perforin or by exposure of Fas ligand *(FasL)* on the T cell surface. The integrin component CD103 is postulated to help retain T cells in epithelial layers by binding to E-cadherin, expressed most strongly in the distal nephron. Macrophages induce local tissue damage through secretion of cytokines, oxygen species, and nitric oxide (delayed-type hypersensitivity response). CD4 T cells secrete cytokines, which induce upregulation of major histocompatibility complex *(MHC)* molecules on epithelial and endothelial cells. CD4 T cells also provide help to B cells for production of alloantibody by engagement of CD40L and production of cytokines. Antigraft antibody is usually directed at MHC molecules, followed by activation of complement. Damaged endothelial cells secrete factors that activate coagulation systems and result in formation of microthrombi. Exposure of tubular cells and glomerular capillary loops to alloimmunity over time results in interstitial fibrosis, tubular atrophy, and glomerulosclerosis. *BM,* Basement membrane; *IFN,* interferon; *IL-2,* interleukin-2; *TCR,* T cell receptor; *TGF,* transforming growth factor; *TNF,* tumor necrosis factor.

Acute Antibody-Mediated Rejection

Acute AMR is recognized as a distinct clinicopathologic entity and may occur with or without a component of TCMR (see Fig. 100-8). Although typically a response to donor HLA antigens expressed on endothelial cells, AMR can occur to non-HLA antigens. Examples include ABO blood group antigens and the putative endothelial alloantigens, as suggested by the rare occurrence of AMR in HLA-matched nonidentical sibling grafts. Even autoantibodies have been implicated, such as those to angiotensin II type 1 receptors. The kidney typically shows an accumulation of neutrophils and monocytes in peritubular and glomerular capillaries, although the infiltrate can be quite sparse.[35] Tubulitis and endarteritis are generally minimal, unless a component of TCMR is present. FOXP3+ Tregs are more rare in the AMR infiltrate than that of TCMR,[36] perhaps indicating a factor in the poorer prognosis. A subset of acute AMR that can result in immediate graft failure is hyperacute rejection, which is caused by the presence of preformed anti–donor HLA antibody in sensitized recipients or of antibodies to mismatched ABO blood group loci. This type of AMR is rare now that crossmatching practices and/or desensitization protocols are routinely used by transplant centers.

Alloantibodies are cytotoxic through their ability to activate complement. The classical pathway appears most relevant; other pathways have not been shown to participate in acute or chronic AMR. C4d is an inactive fragment of C4b, an activation product of the classical pathway. C4b and C4d contain an occult sulfhydryl group that forms a covalent thioester bond with nearby proteins bound in the tissue after activation by Ig and C1. No functional role for C4d has been reported, but it remains in the tissue for several days after Ig and C1 have been released. C4d deposition is strongly associated with circulating antibody to donor HLA class I or II antigens and is currently the best single marker of complement-fixing circulating antibodies to the endothelium.

The acute effects of complement are well described and include chemoattraction of neutrophils and macrophages via C3a and C5a, vasospasm through the release of prostaglandin E_2 from macrophages, and edema through the release of histamine from mast cells. C3a and C5a increase endothelial adhesion molecules and various cytokines and chemokines.[37] The membrane attack complex, C5b-9, causes lysis of endothelial cells. Alloantibodies may also induce cell damage through complement-independent pathways by recruitment of leukocytes with Fc receptors (CD16 most commonly), including NK cells and macrophages (antibody-dependent cellular cytotoxicity). Finally, antibodies without leukocyte or complement participation can activate endothelial cells to produce chemokines and promote rejection in some animal models.[38]

A common feature of all types of AMR is the presence of microthrombi. As a result of antibody-mediated damage, von Willebrand factor is released from the endothelium, leading to platelet aggregation.[39] Animal models indicate that clotting activation is a direct consequence of complement fixation. Activation of endothelial protease-activated receptors by coagulation proteases, including thrombin, leads to the secretion of many proinflammatory cytokines.[40]

Chronic Rejection

Late allograft dysfunction is caused by a combination of alloimmune mechanisms (i.e., chronic rejection) and alloimmune-independent mechanisms, including hypertension, calcineurin inhibitor toxicity, and recurrent disease.[41] Chronic rejection may occur by either cellular or humoral mechanisms, or both. Histologic features characteristic of chronic rejection are transplant glomerulopathy, peritubular capillaropathy (see later), transplant arteriopathy, and, less specifically, tubular atrophy and interstitial fibrosis.

Transplant glomerulopathy is defined by the widespread duplication or multilamination of the glomerular basement membrane (GBM), sometimes accompanied by mesangial expansion and accumulation of mononuclear cells in glomerular capillaries. GBM duplication may be caused by a number of insults to the allograft glomerulus, including recurrent or *de novo* immune complex glomerular disease and thrombotic microangiopathy. However, it is believed that chronic antibody-mediated injury predominates, because the majority of cases of transplant glomerulopathy are associated with circulating antibody to donor class II MHC antigens (sometimes class I antigens), and approximately 30% to 50% of these patients have C4d deposition in the peritubular capillaries (PTCs).[42] It is believed that the absence of C4d deposition in the remainder of patients represents intermittent antibody involvement or antibodies directed at non-MHC antigens that do not fix complement.

Similar to findings in transplant glomerulopathy, multilamination of PTCs can be demonstrated by electron microscopy (peritubular capillaropathy). It is believed that repeated episodes of antibody-mediated injury to the endothelium result in repair mechanisms that are characterized by duplication of the basement membrane. What leads to episodic antibody injury is unknown, but it may represent the fluctuating donor-specific antibody levels observed in some patients followed longitudinally. Neointimal thickening can be observed in either C4d-positive or C4d-negative chronic rejection. Known as *transplant arteriopathy,* this lesion is characterized histologically by thickening of the arterial intima without duplication of the elastica (in contrast to fibroelastic thickening seen in hypertension.) Macrophages and T cells may sometimes be demonstrated within the thickened intima, providing evidence of cell-mediated immunologic activity.

Although not specific for rejection, interstitial fibrosis with tubular atrophy is another important histologic feature of chronically rejected allografts. One putative mechanism of fibrosis is by epithelial-mesenchymal transition (EMT) of tubular cells to activated myofibroblasts that migrates into the interstitium.[43] Steps in this conversion include loss of cell-cell adhesion, loss of E-cadherin, acquisition of α–smooth muscle actin, actin reorganization, tubular basement membrane disruption, cell migration, and production of profibrotic molecules.

The current criteria for chronic active AMR are histologic evidence of chronic injury (in the absence of other possible causes), immunopathologic evidence of antibody action (i.e., C4d staining), and evidence of circulating antibody reactive to the donor. Chronic AMR appears to arise through a series of stages.[35] The first common event is alloantibody production (stage I), followed by antibody interaction with alloantigens resulting in the deposition of C4d in the PTCs and glomeruli (stage II), followed by pathologic changes (stage III), and followed finally by graft dysfunction (stage IV). Although the factors promoting progression from stage 1 to stage IV are not currently understood, the hypothesized stages provide a useful organizing structure for ongoing clinical trials to intervene in the earlier stages (I or II).

TRANSPLANTATION TOLERANCE

Transplantation tolerance is a state characterized by the absence of a destructive immune response in the recipient toward a well-functioning donor allograft, with a fully intact immune system and no exogenous immunosuppression.[44,45] As with self-tolerance, transplantation tolerance is achieved through control of T cell reactivity

by both central and peripheral mechanisms. Central tolerance involves thymic deletional mechanisms that eliminate T cells with reactivity against self-antigens (or donor antigens in the case of transplantation tolerance) and positive selection of T cells without such reactivity. In experimental transplant models, central tolerance is achieved by elimination of the preexisting mature T cell population by irradiation and/or cytotoxic agents, followed by infusion of donor hematopoietic progenitor cells. Reconstituted donor antigen "reeducates" the thymus to delete developing T cells with antidonor reactivity, leading to a state of chimerism, in which both donor and recipient cells coexist. Translating this approach to the clinical setting, however, requires a functional thymus, which may not be present in the adult human.

Peripheral tolerance mechanisms include deletion, anergy, and regulation. With self-tolerance, these mechanisms serve to prevent deleterious autoimmune responses from T cells that escape central deletion. Various approaches to induce peripheral transplant tolerance with the goal of inhibiting deleterious alloimmune responses are currently under investigation, including costimulatory blockade, pharmacologic manipulation of DCs, and the induction of donor antigen–specific Tregs. One of the most significant hurdles to the development of clinical tolerance strategies is the lack of reproducible immune monitoring assays to detect the presence or absence of tolerance, which would determine when immunosuppressive medications could be safely withdrawn. Although transplantation tolerance is not yet a clinical reality, progress in the field is being made.[46,47]

CHAPTER 101

Immunosuppressive Medications in Kidney Transplantation

Mabel A. Bodell, Karl L. Womer, and Hamid Rabb

Much of the success of kidney transplantation is a result of advances in immunosuppressive medications that are used during the induction and maintenance phases and for treatment of acute rejection.[1] The term *maintenance immunosuppression* is usually used to describe drug regimens consisting historically of small-molecule agents that are administered to stable kidney transplant recipients. Increasingly, community nephrologists and primary care physicians are becoming involved in the care of stable kidney transplant recipients. In contrast, biologic agents that are used as induction protocols before the maintenance stage or for the treatment of acute rejection episodes are commonly managed by transplant surgeons and nephrologists in inpatient settings. This chapter discusses the immunosuppressive agents that are commonly used for prevention of rejection in renal transplantation by most transplant centers, with specific emphasis on their biologic mechanisms of action, pharmacokinetics, and side effect profile. These agents are divided into small-molecule drugs and biologic agents for the purposes of this discussion.

SMALL-MOLECULE DRUGS

Corticosteroids

Corticosteroids have been a cornerstone of transplant immunosuppression for the past 50 years, both as maintenance immunosuppression and for treatment of acute rejection.

Mechanism of Action

Corticosteroids suppress production of numerous cytokines and vasoactive substances, including interleukin (IL)–1, tumor necrosis factor α (TNF-α), IL-2, major histocompatibility complex class II, chemokines, and proteases. Corticosteroids also cause neutrophilia (often with a left shift), but neutrophil chemotaxis and adhesion are inhibited. They also affect nonhematopoietic cells including intrarenal cells.

Corticosteroids act as agonists of glucocorticoid receptors but at higher doses have receptor-independent effects. Corticosteroid receptors (CRs) belong to a family of ligand-regulated transcription factors called *nuclear receptors*. CRs are normally present in the cytoplasm in an inactive complex with heat shock proteins. The binding of corticosteroids to the CRs dissociates heat shock protein (HSP) from the CR and forms the active corticosteroid-CR complex, which migrates to the nucleus and dimerizes on palindromic DNA sequences in many genes; this action is called the *corticosteroid response element*. The binding of CR in the promoter region of the target genes can lead to either induction or suppression of gene transcripts (e.g., of cytokines). CRs also exert effects by interacting directly with other transcription factors independent of DNA binding.

A key way by which corticosteroids regulate immune responses is by regulation of the transcription factors activator protein 1 (AP-1) and nuclear factor κB (NF-κB). Normally, NF-κB is present as an inactive complex with inhibitor of nuclear factor κB (IκB), but it can be released by IκB kinase. Corticosteroids stimulate IκB, which then competes with the IκB–NF-κB complex for degradation by the IκB kinase. Corticosteroids also stimulate lipocortin, which inhibits phospholipase A_2, thereby inhibiting the production of leukotrienes and prostaglandins. The total immunosuppressive effect of corticosteroids is complex, reflecting effects on cytokines, adhesion molecules, apoptosis, and activation of inflammatory cells.

Pharmacokinetics

The major corticosteroids used are oral prednisone (or prednisolone) and intravenous methylprednisolone. The oral agents have good oral bioavailability and short half-lives (60 to 180 minutes) but long biologic half-lives (18 to 36 hours). Corticosteroids are eliminated by hepatic conjugation and are excreted by the kidneys as inactive metabolites. Coadministration of inducers of enzymes that metabolize corticosteroids (e.g., phenytoin, rifampin) decreases their half-life, whereas concomitant use of P-450 3A4 inhibitors (e.g., ketoconazole) has the opposite effect. Because corticosteroid levels are not routinely monitored, dosage adjustment during concurrent therapy with these medications becomes problematic. For treatment of acute rejection, pulse doses of 250 to 1000 mg of methylprednisolone are typically used, with no evidence that the higher dosage is more efficacious.

Side Effects

Side effects of corticosteroid therapy are common and associated with significant morbidity, particularly cataracts, osteoporosis, and avascular necrosis of the femoral heads (Table 101-1). Other side effects include hypertension, hyperglycemia, hyperlipidemia, cushingoid features, psychiatric disturbances, sleep disorders, peptic ulcer disease, pancreatitis, colonic perforation, increased appetite with weight gain, growth retardation, and myopathy. Infection risk is also increased and is excessive if high-dose pulse therapy is prolonged. It is interesting to note that corticosteroids are not associated with increased incidence of malignant disease. Although corticosteroids are generally considered safe in pregnancy, fetal adrenal suppression has been reported.

Calcineurin Inhibitors

Calcineurin inhibitors (CNIs), including cyclosporine and tacrolimus, are fungus-derived small molecules that are the mainstays of current maintenance immunosuppressive regimens. Considerable variability exists in their pharmacokinetics, interactions, and side

Common Side Effects of Small-Molecule Immunosuppressive Medications							
	Cyclosporine	**Tacrolimus**	**Mycophenolate**	**Azathioprine**	**Corticosteroids**	**mTOR Inhibitors**	**Leflunomide**
Renal	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia			HTN, hypokalemia, diuretic resistance	Synergistic nephrotoxicity with CNIs, delayed recovery from ATN, proteinuria, hypokalemia, HTN	
Gastrointestinal		Diarrhea, abdominal pain	Diarrhea, nausea and vomiting, gastritis, esophagitis, oral and colonic ulcers	Nausea and vomiting, hepatotoxicity, pancreatitis	Peptic ulcers, gastritis, esophagitis, diarrhea, colonic perforation	Diarrhea	Nausea, diarrhea, hepatitis
Hematologic	Thrombotic microangiopathy	Thrombotic microangiopathy	Anemia, leukopenia, thrombocytopenia	Anemia, leukopenia, thrombocytopenia	Leukocytosis, polycythemia	Thrombotic microangiopathy, anemia, thrombocytopenia	Anemia, leukopenia
Metabolic	Hyperlipidemia, hyperuricemia, gout, glucose intolerance	New onset diabetes			Hyperlipidemia, hyperuricemia, hyperglycemia, osteoporosis, vascular necrosis, increased appetite and weight gain	Hyperlipidemia	
Cosmetic	Gingival hyperplasia, coarsened facial features	Alopecia			Hirsutism, acne, cushingoid facies, buffalo hump	Impaired wound healing, oral ulcers	Alopecia
Neuromuscular	Encephalopathy, insomnia, myopathy, tremors	Encephalopathy, insomnia, myopathy, tremors			Psychosis, insomnia, myopathy	Reflex sympathetic dystrophy	
Other	Edema	Myocardial hypertrophy	Viral infections, pulmonary edema in elderly, progressive multifocal leukoencephalopathy		Cataracts	Lymphocele, interstitial pneumonitis, rash, edema	Rash

Table 101-1 Common side effects of small-molecule immunosuppressive medications. *ATN,* Acute tubular necrosis; *CNIs,* calcineurin inhibitors; *HTN,* hypertension; *mTOR,* mammalian target of rapamycin; *RTA,* renal tubular acidosis.

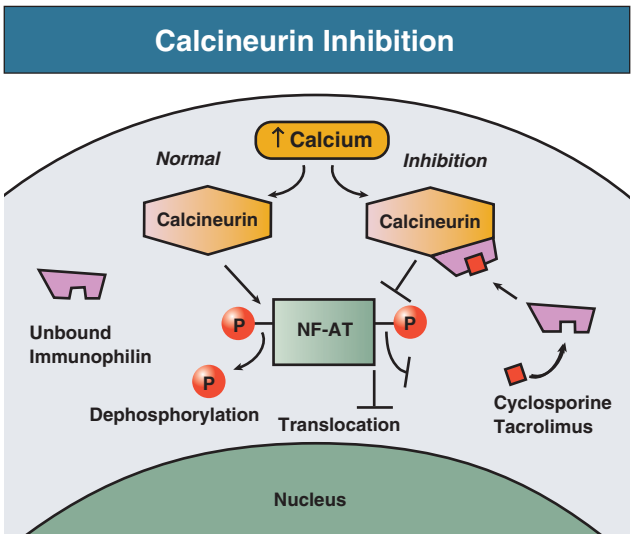

Figure 101-1 Calcineurin inhibition. During normal T cell activation, calcium release activates calcineurin's phosphatase activity, causing dephosphorylation of the transcription factor, nuclear factor of activated T cells *(NF-AT),* and subsequent translocation to the nucleus. Cyclosporine and tacrolimus form a complex with immunophilins (cyclophilin or FK-binding protein 12, respectively), which bind calcineurin and sterically inhibit the phosphatase activity, preventing dephosphorylation and nuclear translocation of NF-AT.

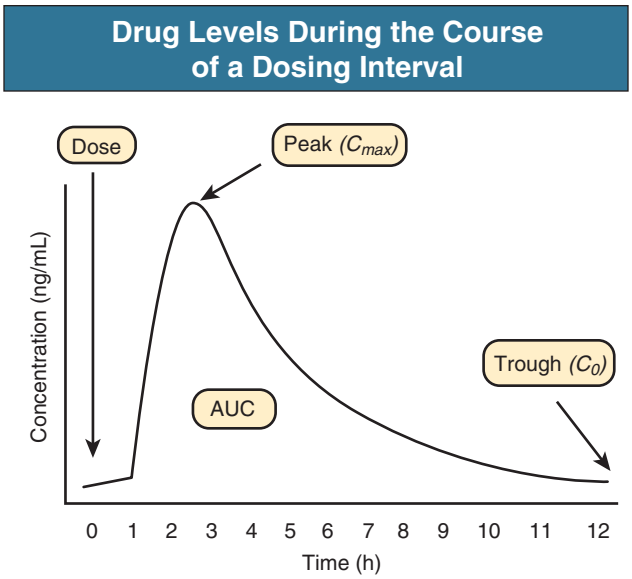

Figure 101-2 Drug levels during the course of a dosing interval. The drug concentration is lowest just before the dose is taken (C_0), then rises to a peak concentration at a certain time after the dose (C_{max}). The area under the concentration-time curve (AUC) describes total drug exposure during the entire administration interval.

effect profiles, which raises the question of which agent to use in the individual patient. Cyclosporine is a cyclic, lipophilic undecapeptide with several *N*-methylated amino acids, which may explain its resistance to inactivation in the gastrointestinal tract. Tacrolimus is a macrolide lactone antibiotic. Both drugs are highly soluble in lipids.

Mechanism of Action

Both CNIs exert their effect by binding to cytoplasmic proteins called *immunophilins* (Fig. 101-1). Cyclosporine binds to cyclophilin, whereas tacrolimus binds to FK-binding protein 12 (FKBP12).[2] Such binding enhances the immunophilin's affinity for and subsequent inhibition of calcineurin, which is a calmodulin-activated serine phosphatase important for dephosphorylation of inactive nuclear factor of activated T cells (NF-AT). Nuclear translocation of dephosphorylated (active) NF-AT, in association with other transcription factors, initiates downstream events leading to T cell activation (see Chapter 100). The tacrolimus-FKBP12 active complex inhibits calcineurin with greater molar potency than the corresponding cyclosporine complex. Cyclosporine and tacrolimus can interfere with activation of calcineurin on substrates other than NF-AT, which likely explains many of the side effects of calcineurin inhibition. Treatment with CNIs also causes upregulation of the cytokine transforming growth factor β (TGF-β), which has significant immunosuppressive properties but also promotes the deposition of matrix proteins and tissue fibrosis. Finally, these two agents can suppress the immune response by calcineurin-independent pathways as well. This mechanism generally involves blockade of intracellular signaling pathways specific for T cells. The ability of these agents to interfere with two distinct mechanisms of T cell activation contributes to their highly specific immunosuppressive properties.

Pharmacokinetics, Monitoring, and Drug Interactions

After a dose of CNI, there is an initial absorptive phase, during which blood concentrations reach a peak level (C_{max}).[3] Typically, C_{max} occurs during the first 2 to 3 hours after the dose and corresponds to the time of maximum calcineurin inhibition. Drug levels then fall as a result of metabolism (also known as the *elimination phase*) until they are at the lowest, or trough, level (C_0) immediately before the next dose. The total drug exposure throughout the period from one dose until the next is the area under the concentration-time curve (AUC; Fig. 101-2). For both CNIs, most of the interpatient and intrapatient variability occurs in the absorption rather than in the elimination phase.

The oil-based formulation of cyclosporine requires solubilization in bile and is plagued by highly variable and unpredictable bioavailability The microemulsion preparation of cyclosporine (modified) has enhanced bioavailability and less dependence on bile secretion. In blood, cyclosporine resides primarily in erythrocytes (60% to 70%) and leukocytes, with some binding to lipoproteins and, to lesser extent, other plasma proteins. Cyclosporine is metabolized primarily by CYP3A4, a member of the cytochrome P-450 superfamily. Metabolism occurs mostly in the liver. Interindividual differences in CYP3A4 activity and the large number of exogenous and endogenous substances capable of altering its function and expression explain the wide variation in clearance rates. One factor is the multidrug resistance 1 gene product, P-glycoprotein, which is variably expressed in the intestine and reduces the absorption of several xenobiotics, including CNIs, by transport out of intestinal epithelial cells. The average half-life of cyclosporine is about 19 hours, with excretion primarily in bile. Generic formulations of cyclosporine modified exist, although they may not have identical pharmacokinetics and therefore may not be readily interchangeable.

The absorption of tacrolimus, like that of cyclosporine, is highly variable; bioavailability ranges from 5% to 67%. Absorption is not bile dependent but does depend on gastrointestinal transit time and is affected by the presence or absence of food as well as the lipid content of food. Clearance appears to be faster in children, necessitating administration of higher or more frequent doses. Ethnic differences exist as well, with African Americans and Latin Americans requiring higher doses than Caucasians to achieve equivalent therapeutic levels. These differences may in part be caused by expression

of alternative subtypes of CYP3A (e.g., CYP3A5). In blood, tacrolimus distributes primarily to erythrocytes, with whole-blood concentrations 10 to 30 times higher than in plasma. In contrast to cyclosporine, no lipoprotein binding occurs. Tacrolimus has 20- to 30-fold higher potency than cyclosporine on a molecular weight basis. Similar to cyclosporine, metabolism occurs through the CYP3A4 system, with pharmacokinetics also affected by intestinal P-glycoprotein. Both CNIs are generally administered twice daily.

Because of their narrow therapeutic index, the variability of concentrations among patients after a dose, and the potential for drug interactions, monitoring of CNIs is required to ensure both safety and adequacy. Both cyclosporine and tacrolimus bind to cells and to plasma components (primarily lipoproteins for cyclosporine and albumin for tacrolimus) in the blood and therefore must be assayed in the whole blood. Four assays are currently used to monitor levels of CNIs in the blood: high-performance liquid chromatography (HPLC), monoclonal radioimmunoassay (RIA), monoclonal and polyclonal fluorescent polarization immunoassays, and the specific enzyme-multiplied immunoassay. Cyclosporine trough levels measured by HPLC or RIA are comparable because both techniques measure levels of the parent compound only. However, these concentrations are one-third lower compared with concentrations measured by techniques that detect the parent compound plus its metabolites.

Given the complementary influence of both CYP3A4 and P-glycoprotein on the pharmacokinetic profiles of CNIs, it is assumed that CNI-drug interactions are similar. It is interesting to note that drugs that competitively inhibit CYP3A4 activity, such as ketoconazole, usually also inhibit P-glycoprotein, thereby increasing the bioavailability of CNIs and potential for toxicity. Likewise, drugs such as phenobarbital that increase CYP3A4 levels tend to upregulate P-glycoprotein, decreasing overall bioavailability. In this case, the likelihood of rejection increases. Despite similar drug interactions, the age-related and ethnic differences in pharmacokinetics between the two CNIs are likely to influence the degree and importance of such interactions. See Table 101-2 for common interactions.

Drugs and Other Substances That Interact with Calcineurin Inhibitors

Increase Blood Levels (P450-3A4 and/or P-Glycoprotein Inhibitors)	Decrease Blood Levels (P450-3A4 and/or P-Glycoprotein Inducers)
Ketoconazole	Rifampin
Fluconazole	Rifabutin
Itraconazole	Phenytoin
Voriconazole	Carbamazepine
Erythromycin	Phenobarbital
Clarithromycin	St John's wort
Diltiazem	Caspofungin
Verapamil	
Nicardipine	
Cimetidine	
Methylprednisolone	
Metronidazole	
Ezetimibe	
Metoclopramide	
Fluvoxamine	
Human immunodeficiency virus (HIV) protease inhibitors	
Lovastatin	
Atorvastatin	
Simvastatin	
Grapefruit juice	
Chamomile	
Wild cherry	

Table 101-2 Drugs and other substances that interact with calcineurin inhibitors.

Side Effects

Cyclosporine and tacrolimus have similarities and differences in their toxicity profiles (see Table 101-1). Both can cause nephrotoxicity, hyperkalemia, hypomagnesemia and hypophosphatemia (secondary to urinary loss), renal tubular acidosis (type 4), hypertension, diabetes, and neurotoxicity. Certain side effects, such as gingival hyperplasia, hirsutism, hypertension, hyperuricemia, and hyperlipidemia, are more common with cyclosporine, whereas tremor and glucose intolerance are more common with tacrolimus. Cyclosporine may also be associated with coarsening of facial features, especially in children, and bone pain responsive to calcium channel blockers. Tacrolimus, especially in combination with mycophenolate mofetil (MMF), has been suspected of inducing more BK virus nephropathy.

The most common and vexing problem with CNIs is nephrotoxicity, with the importance evident from cardiac and liver transplant recipients, in whom large doses of CNIs are associated with progression to end-stage renal disease. Both reversible hemodynamic and irreversible structural components underlie the nephrotoxicity of CNIs. Reversible vasoconstriction is caused by direct vascular effects but is also due to activation of the renin-angiotensin system (RAS), endothelin, thromboxane, and the sympathetic nervous system. Over time, chronic renal injury occurs, which is notable for afferent arterial hyalinosis and tubulointerstitial fibrosis. It is presumed that these lesions are the result of prolonged renal vasoconstriction with ischemia. Experimentally, chronic cyclosporine nephropathy is exacerbated by sodium restriction and volume depletion, which stimulates the RAS, and can be ameliorated by angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Cyclosporine toxicity and to a lesser extent tacrolimus toxicity are potentiated in combination with sirolimus and everolimus. Finally, CNIs in high doses can cause thrombotic microangiopathy (TMA), probably by direct endothelial cell injury and dysfunction.

Mycophenolate

Mycophenolate mofetil and enteric-coated mycophenolate sodium (EC-MPS) are important components of immunosuppressive regimens that are associated with some of the most successful outcomes in kidney transplantation.[4] Because of its well-documented efficacy and acceptable side effect profile, MMF has become by far the most frequently used antiproliferative agent.

Mechanism of Action

The immunosuppressive effects of both these agents are likely to be mediated through the active metabolite mycophenolic acid (MPA). MMF is a morpholinoethyl ester of MPA, a potent reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), isoform 2. EC-MPS is a salt that combines an acid—MPA—with a base—sodium. The enteric coating delays MPS release so that the MPA is absorbed in the small intestine rather than in the stomach. MPA noncompetitively inhibits IMPDH, which is the rate-limiting enzyme in the *de novo* synthesis of guanosine monophosphate (GMP). Inhibition of IMPDH creates a relative deficiency of GMP and a relative excess of adenosine monophosphate (AMP). GMP and AMP levels act as a control on *de novo* purine biosynthesis; therefore, MPA, by inhibiting IMPDH, creates a block in *de novo* purine synthesis that selectively interferes with proliferative responses of T and B cells. Some other cell types, including gastrointestinal epithelial cells, use the *de novo* pathway. Thus, MPA may act directly to inhibit replication of gastrointestinal epithelial cells, leading to disruption of fluid

absorption and diarrhea. However, most other cell types, including neurons, depend primarily on the alternative pathway for DNA synthesis and cell division and thus are relatively spared from toxicity.

Pharmacokinetics

Mycophenolate mofetil, being a prodrug of MPA, is absorbed rapidly and completely from the gastrointestinal tract and undergoes extensive presystemic de-esterification to become MPA, the active form. Food intake can delay the rate of MMF absorption but does not affect the extent. However, coadministration of antacids or cholestyramine decreases absorption by approximately 20% and 40%, respectively. EC-MPS has shown bioavailability equivalence as well as similar efficacy to that of MMF despite reaching higher levels with the use of proton pump inhibitors (PPIs). MPA undergoes enterohepatic circulation, and its plasma concentration shows a secondary peak at 6 to 12 hours after intravenous or oral administration. The mean contribution of enterohepatic circulation to the overall AUC of MPA is 37% (range, 10% to 61%). The majority of MPA is metabolized in the liver through a phase II glucuronidation process. The major metabolite of MPA is the pharmacologically inactive 7-*O*-glucuronide metabolite (MPAG), although two other metabolites, MPA-acyl-glucuronide (AcMPAG) and MPA-phenyl-glucoside (glucoside-MPA), are isolated from the plasma of renal transplant patients. AcMPAG has shown *in vitro* pharmacologic activity (inhibition of IMPDH) as well as proinflammatory effects and potentially is responsible for the gastrointestinal toxicity of MPA.

The glucuronide metabolites are excreted into the bile, a process that is mediated by the multidrug resistance–related protein 2 (MRPR2), then undergo de-glucuronidation back to MPA by enzymes that are produced by colonic bacteria. Blockade of MRPR2 by an inhibitor, such as cyclosporine but not tacrolimus, decreases the biliary excretion of MPAG and increases plasma MPAG levels. This eventually leads to lower plasma levels of MPA because the glucuronide metabolites no longer can be reabsorbed as MPA by enterohepatic cycling. Thus, tacrolimus-treated patients have higher exposure to MPA than cyclosporine-treated patients do, and it is possible that tacrolimus results in greater intestinal exposure to the metabolites of MPA because of greater enterohepatic circulation.[5] The ultimate elimination pathway for the glucuronide metabolites is through the kidney, and more than 95% of an administered dose eventually is found in the urine as glucuronide metabolites.

For the most part, MMF and EC-MPS have been used exclusively in a fixed-dose regimen. However, studies have established a strong association of MPA AUC and its pharmacologic effects, specifically prevention of acute rejection. Furthermore, considerable interindividual variability is found in MPA AUC and trough concentrations in patients who receive a fixed dose of MMF. These data lend support to recent efforts to evaluate the role of therapeutic drug monitoring in increasing the therapeutic potential of MMF and EC-MPS.

Side Effects

Mycophenolate mofetil and EC-MPS have similar side effect profiles, including gastrointestinal toxicity, bone marrow suppression, and increased infections, especially those of viral cause (see Table 101-1). Gastrointestinal disturbances include oral ulcerations, esophagitis, gastritis, nausea and vomiting, diarrhea, and colonic ulcers. Diarrhea and leukopenia frequently necessitate dose reduction, which can precipitate rejection. Because the metabolites of MPA appear to play a major role in the gastrointestinal disturbances associated with MMF, there is little rationale for enteric coating of the prodrug to reduce these symptoms. In fact, randomized controlled trials have found no significant difference in gastrointestinal adverse events between MMF and EC-MPS.[6,7] MMF is not routinely used during pregnancy because of its teratogenicity in experimental animal models and clinical reports of major fetal malformations (mycophenolate embryopathy).

Azathioprine

The use of azathioprine has decreased dramatically in kidney transplantation with the introduction of MMF. Azathioprine is metabolized in the liver to 6-mercaptopurine and further converted to the active metabolite thioinosinic acid by hypoxanthine-guanine phosphoribosyltransferase. Because allopurinol (a xanthine oxidase inhibitor) will increase the levels of thioinosinic acid, doses of azathioprine must be reduced by two thirds in patients taking allopurinol. More often, MMF is substituted for azathioprine.

Azathioprine suppresses the proliferation of activated T and B cells and reduces the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow. The antiproliferative effect is mediated by the metabolites of azathioprine, including 6-mercaptopurine, 6-thiouric acid, 6-methylmercaptopurine, and 6-thioguanine. These compounds are incorporated into replicating DNA and halt replication. They also block the *de novo* pathway of purine synthesis by formation of thioinosinic acid; this effect confers specificity of action on lymphocytes that lack a salvage pathway for purine synthesis.

The major side effect of azathioprine is bone marrow suppression, leading to leukopenia, thrombocytopenia, and anemia (see Table 101-1). The mean cell volume is commonly increased in patients taking azathioprine, and red cell aplasia can occasionally occur. The hematologic side effects are dose related and usually reversible on dose reduction or temporary discontinuation of the drug. Other common side effects are increased risk of malignant disease (especially of skin cancers), hepatotoxicity, pancreatitis, and hair loss. Azathioprine is generally considered safe in pregnancy.

Mammalian Target of Rapamycin Inhibitors

The mammalian target of rapamycin (mTOR) inhibitors are proliferation signal inhibitors with potent immunosuppressive activity. Sirolimus, also called *rapamycin,* was the first agent used in transplantation and is a macrolide product of a soil fungus found in Easter Island.[8] Everolimus is a rapamycin analogue with similar mechanism of action, immunosuppressive properties, and side effect profile. Although initially used in regimens with the intent of minimizing exposure to CNIs, the mTOR inhibitors have been associated with their own set of toxicities that have prevented their widespread use.

Mechanism of Action

Sirolimus has structural similarity to tacrolimus and binds the immunophilin FKBP12. The affinity of sirolimus for FKBP12 is higher than that of everolimus. mTOR inhibitors do not inhibit calcineurin or the calcium-dependent activation of cytokine genes but instead inhibit cytokine receptor–mediated signal transduction and cell proliferation and block lymphocyte responses to cytokines and growth factors. The sirolimus-FKBP12 or everolimus-FKBP12 complex binds with high affinity a kinase enzyme called *mammalian target of rapamycin* or mTOR, which is a serine-threonine kinase of the phosphatidylinositol 3-kinase pathway that acts during costimulatory and cytokine-driven pathways. mTOR inhibits an inhibitor (4E-BP1) and activates a ribosomal enzyme (p70 S6 kinase), both of which are important for translation of the mRNAs for certain proteins needed for progression from the G_1 phase to the S phase of DNA synthesis. mTOR has been identified as the principal controller of cell growth and proliferation. The sirolimus-FKBP12 complex

inhibits mTOR-mediated signal transduction pathways by blocking postreceptor immune responses to costimulatory signal 2 during G_0 to G_1 transition and to cytokine signaling during G_1 progression. It also inhibits IL-2– and IL-4–dependent proliferation of T and B cells, leading to suppression of new ribosomal protein synthesis and arrest of the G_1-S phase of the cell cycle. Proliferation of nonimmune cells, such as fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells, is also impaired by inhibition of the growth factor–mediated responses (e.g., basic fibroblast growth factor, platelet-derived growth factor, vascular endothelial cell growth factor, and TGF-β). In addition, it has been shown that mTOR contributes to several protein synthesis pathways that could be involved in oncogenesis.

Pharmacokinetics

The oral bioavailability of sirolimus is poor (10% to 16%), with significant interindividual and intraindividual variability. Peak concentrations occur approximately 1 to 2 hours after an oral dose, and sirolimus distributes extensively into tissues, including blood cells. The oral bioavailability of everolimus is higher than that of sirolimus. High-fat meals increase sirolimus levels while decreasing everolimus levels. Because sirolimus has a relatively long half-life (approximately 62 hours), it is reasonable to wait 1 week (approximately three half-lives to achieve steady state) before monitoring sirolimus blood levels after initiation or dose adjustment. Sirolimus is metabolized by the P-450 3A4 isoenzyme and P-glycoprotein system and thus has interactions similar to those described for the CNIs (see Table 101-2). When sirolimus or everolimus is administered simultaneously with cyclosporine, C_{max} and AUC for both compounds are increased. Therefore it is recommended that cyclosporine and mTOR inhibitors be administered 4 hours apart. Cyclosporine clearance may be reduced during concurrent therapy.

Side Effects

The mTOR inhibitors have a wide variety of toxicities (see Table 101-1). The most common adverse effects associated with sirolimus are dose-dependent hyperlipidemia (particularly hypertriglyceridemia), thrombocytopenia, and leukopenia. Other adverse effects include anemia (especially in combination with MMF), impaired wound healing and dehiscence, formation of lymphoceles, oral ulcers, reduced testosterone levels, pneumonitis, and diarrhea. Although not inherently nephrotoxic, the mTOR inhibitors result in renal graft damage through several mechanisms. When it is used in combination with full-dose cyclosporine (and probably also tacrolimus), sirolimus potentiates CNI-induced toxicity. In patients with renal impairment, sirolimus is associated with marked yet potentially reversible proteinuria and worsening of established proteinuria. Sirolimus can also cause delayed recovery from acute tubular necrosis. Finally, cases of TMA have been reported, and there is concern that higher doses of sirolimus may inhibit endothelial cell growth. Sirolimus-based regimens have been associated with a reduced incidence of post-transplantation malignant neoplasms. Some physicians regard sirolimus as the preferred immunosuppressive agent in transplant patients who develop malignant neoplasms, but this is based on limited data about kidney transplant recipients and skin cancer. Sirolimus is not routinely used during pregnancy because of its teratogenicity in experimental animal models, although successful pregnancies have been reported.

Dihydroorotate Dehydrogenase Inhibitors

Leflunomide and its derivative, FK778, are pyrimidine synthesis inhibitors with immunosuppressive as well as antiproliferative effects. These agents inhibit dihydroorotate dehydrogenase, which is a key rate-limiting enzyme in *de novo* pyrimidine synthesis. Unlike other cell types, activated lymphocytes expand their pyrimidine pool by nearly eightfold during proliferation, whereas purine pools increase only twofold. Thus, inhibition of dihydroorotate dehydrogenase prevents lymphocytes from accumulating sufficient pyrimidines to support DNA synthesis.

Leflunomide tablets are 80% bioavailable. After oral administration, leflunomide is metabolized to teriflunomide, which is responsible for essentially all of the activity *in vivo* and is monitored during therapy. Metabolism occurs in the liver, with excretion in the urine and bile. Because of its very long half-life (approximately 2 weeks), a loading dose of 100 mg for 3 to 5 days is generally used to reach steady-state levels quickly. Side effects include gastrointestinal adverse events, alopecia, bone marrow suppression, severe hepatitis, interstitial lung disease, and life-threatening skin reactions. Leflunomide use is not safe during pregnancy, and unless female leflunomide users receive cholestyramine therapy to eliminate the drug from the body, pregnancy must be avoided for 2 years after discontinuation. Although it is not approved for use in kidney transplantation, leflunomide has recently been assigned orphan drug status for the prevention of rejection in solid organ transplantation, largely on the basis of modest antiviral activity *in vitro* against BK virus and cytomegalovirus. However, the efficacy and safety of leflunomide have not been completely assessed in well-controlled and adequate studies. Furthermore, the manufacturers of FK778 discontinued development because of a lack of benefit over current options with regard to prevention of rejection and treatment of BK virus nephropathy.

BIOLOGIC AGENTS

Biologic agents in the form of polyclonal antibodies and monoclonal antibodies (mAbs) are frequently used in kidney transplantation either as induction therapy or for the treatment of rejection. Polyclonal antibodies are derived from horses or rabbits; historically, mAbs have been murine in origin. However, because foreign proteins can elicit an immune response, there has been an attempt to replace murine monoclonal products with humanized or chimeric mAbs (Fig. 101-3). Humanized antibodies are produced by merging the DNA that encodes the antigen-binding portion of a monoclonal mouse antibody with human antibody–producing DNA. Mouse hybridomas are then used to express this DNA to produce hybrid antibodies that are not as immunogenic as the murine variety. Chimeric antibodies use the same strategy but for the entire variable region and thus are more immunogenic than humanized antibodies. Polyclonal antibodies and mAbs can be divided further into two groups: depleting agents and immune modulators.

Polyclonal Antilymphocyte Sera

Polyclonal antilymphocyte agents are produced by immunizing animals with human thymus–derived lymphoid cells. Although rabbit antithymocyte globulin (ATG) is currently the preferred preparation, equine preparations have historically been used. Most regimens involve daily intravenous administration of ATG for 5 to 7 days either as induction therapy or for treatment of corticosteroid-resistant rejection. ATG contains antibodies that react against a variety of targets, including red blood cells, neutrophils, dendritic cells, and platelets. ATG binds to multiple epitopes on the surface of T cells and induces a rapid lymphocytopenia by several mechanisms, including complement-dependent cytolysis, cell-dependent phagocytosis, and apoptosis. ATG is a potent immunosuppressive, and

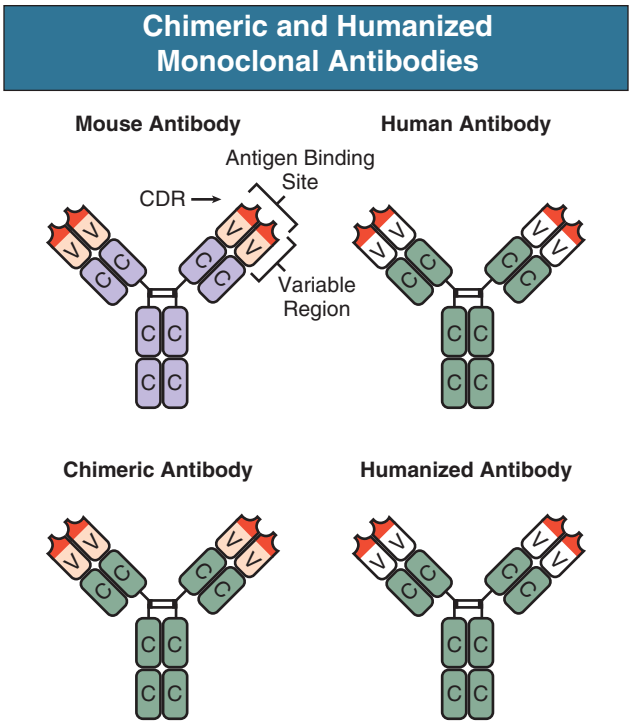

Figure 101-3 Chimeric and humanized antibodies. Chimeric antibodies consist of human constant *(C)* regions and mouse variable *(V)* regions. A chimeric antibody therefore retains the antigen binding site of the mouse antibody but with fewer amino acid sequences foreign to the human immune system than a standard mouse antibody. Humanized monoclonal antibodies retain only the minimum necessary parts of the mouse antibody for antigen binding, the complementarity-determining region (*CDR, highlighted in red*), and therefore are even less immunogenic in the human host.

T- and B-lymphocyte counts can remain depressed up to 24 hours after administration. The lack of specificity coupled with marked immunosuppression increases the risk of infection and malignant neoplasms. As polyclonal agents are xenogeneic proteins, they may elicit a number of side effects, including fever and chills. The initial lysis and activation of T cells that follow ATG administration may generate significant first-dose effects, with release of TNF-α, interferon-γ (IFN-γ), and other cytokines. Less commonly, ATG can induce a serum sickness–like syndrome and rarely acute respiratory distress syndrome (ARDS).

Murine Monoclonal Anti-CD3 Antibody

OKT3, a murine IgG2a mAb targeting the ε chain of the CD3–T cell receptor complex, was used for the treatment of acute rejection but is no longer available.

Humanized Monoclonal Anti-CD52 Antibody

Alemtuzumab is a humanized IgG1 mAb directed against CD52, a glycoprotein present on circulating T and B cells, monocytes-macrophages, NK cells, and granulocytes. Although it is currently approved only for the treatment of B cell chronic lymphocytic leukemia, alemtuzumab has been used as an induction agent in renal transplantation, given its powerful depletional properties and favorable cost profile compared with other induction agents. Treatment results in a rapid and effective depletion of peripheral and central lymphoid cells, which may take months to return to pretransplantation levels. Side effects of alemtuzumab include first-dose reactions, neutropenia, anemia, and, rarely, pancytopenia and autoimmunity (e.g., hemolytic anemia, thrombocytopenia, and hyperthyroidism). The risks of immunodeficiency complications such as infection and malignant neoplasia with alemtuzumab are still not clear, and additional controlled trials are necessary to establish dosing, safety, and efficacy.

Monoclonal Anti-CD25 Antibody

The α subunit of IL-2R (CD25) is upregulated on activated T cells and leads to the expression of high-affinity IL-2R that on engagement by IL-2 triggers the activated T cell to undergo proliferation. Basiliximab is a chimeric mAb with specificity for CD25; it induces relatively mild immunosuppression and is used as an induction agent to prevent rejection[9,10] but not to treat established rejection. Although the exact mechanism of action is not fully understood, it is clear that significant depletion of T cells does not play a major role. Saturation of the IL-2R α subunit persists for up to 25 to 35 days after treatment with basiliximab. Although saturation is important as a determinant of minimal blood concentrations, it is not predictive of rejection. No major side effects have been associated with anti-CD25 therapy.

B Cell–Depleting Monoclonal Anti-CD20 Antibody

Rituximab is an engineered chimeric mAb that contains murine heavy- and light-chain variable regions directed against CD20 plus a human IgG1 constant region.[11] The CD20 antigen, a transmembrane protein, is found on immature and mature B cells as well as on malignant B cells. CD20 mediates proliferation and differentiation of B cells. Rituximab directly inhibits B cell proliferation and induces apoptosis and lysis by complement-dependent cytotoxicity, antibody-dependent cell cytotoxicity, and activation of tyrosine kinases as a direct effect of the antibody's binding to its CD20 ligand. Rapid and sustained depletion of circulating and tissue-based B cells occurs after intravenous administration, and recovery does not begin until approximately 6 months after completion of treatment. Although plasma cells are usually CD20 negative, many are short-lived and require replacement from CD20-positive precursors. In addition, CD20-positive B cells can act as secondary antigen-presenting cells (APCs), thereby enhancing T cell responses. Thus, by targeting CD20 on precursor B cells, rituximab decreases the production of activated B cells and limits their antibody production as well as antigen presentation capability.

Most adverse events are first-infusion effects, such as fevers and chills, and are generally of mild severity. Moreover, these adverse effects occur less frequently during subsequent infusions. Viral infections, including reactivation of hepatitis B virus and JC virus (progressive multifocal leukoencephalopathy [PML]), have been reported, although it is not known whether these events are specific to the agent or instead reflect the overall state of immunosuppression. Antichimeric antibodies develop in some patients, but their true incidence and therapeutic significance are uncertain.

Rituximab has been used in kidney transplantation to treat antibody-mediated rejection as well as in combination with intravenous immunoglobulin (IVIG) to reduce high-titer anti-HLA antibodies in highly sensitized patients awaiting renal transplantation.[12] Rituximab is also used as induction therapy after desensitization therapy for ABO blood group–incompatible and high-risk positive-crossmatch kidney transplantation. Finally, rituximab is often used to treat post-transplantation lymphoproliferative disease.

Intravenous Immunoglobulin

Intravenous immunoglobulin products are known to have powerful immunomodulatory effects on inflammatory and autoimmune conditions. The mode of action of IVIG is not understood. In renal transplantation, the most important effect appears to be a reduction of alloantibodies through inhibition of antibody production and increased catabolism of circulating antibodies. Additional potential mechanisms include inhibition of complement-mediated injury, inhibition of inflammatory cytokine generation, and neutralization of circulating antibodies by anti-idiotypes.

Side effects related to IVIG administration include minor self-limited reactions, such as flushing, chills, headache, myalgia, and arthralgia. Rarely, anaphylactic reactions may occur. Delayed reactions include severe headache and aseptic meningitis, which respond to analgesics. More recently, severe thrombotic events have been linked to the administration of IVIG products. Of concern to renal transplant recipients is osmotic injury of the proximal tubular epithelium after administration of sucrose-containing IVIG preparations. This tubular injury is self-limited and can be minimized or avoided by use of sucrose-free preparations.

In combination with plasma exchange, IVIG appears to offer significant benefits in the desensitization of positive-crossmatch and ABO-incompatible patients to allow successful transplantation as well as in the treatment of antibody-mediated rejection. Alone or in combination with rituximab, IVIG has been successful in the desensitization of highly sensitized wait-listed patients to increase the chances of finding a compatible donor.

Belatacept

Costimulation blockade is an immunosuppression alternative for kidney transplant recipients. Belatacept, a first-in-class costimulation blocker, is a fusion protein that binds to CD80 and CD86 on APCs and prevents kidney transplant rejection. It is for intravenous use only. It affects the CD28 pathway as well as the cytotoxic T-lymphocyte antigen 4 (CTLA-4) pathway, the latter of which is required for the function of T regulatory cells (Tregs) and tolerance of transplanted tissue. Patients treated with belatacept had higher rates of acute rejection during the first year of treatment in comparison with cyclosporine-treated patients. Belatacept seems to have a better metabolic risk profile and preservation of GFR. It is approved only for Epstein-Barr virus (EBV)–seropositive patients, because of increased risk of post-transplant lymphoproliferative disorder (PTLD), especially of the central nervous system in EBV-seronegative patients.[13] There is also increased risk of PML, an often progressive and fatal CNS infection caused by the JC virus, a polyomavirus. The most common adverse reactions observed are anemia, leukopenia, and gastrointestinal symptoms, as well as hypokalemia or hyperkalemia. It is now used in *de novo* renal transplant recipients as well as for conversion from CNIs.

Other Agents Used

Two other agents are increasingly used in transplantation.

Bortezomib

Bortezomib is an antineoplastic agent originally approved for the use in plasma cell dyscrasias such as multiple myeloma and several types of lymphomas. Bortezomib inhibits proteasomes, enzyme complexes that regulate protein homeostasis. Specifically, it reversibly inhibits chymotrypsin-like activity at the 26S proteasome, leading to activation of signaling cascades, cell-cycle arrest, and apoptosis. It targets mature rapidly proliferating antibody-producing plasma cells, but also interferes with T cell function and interleukin and TNF production. It has been used for the treatment of both primary and refractory antibody-mediated rejection and in desensitization protocols to reduce donor-specific antibody (DSA) levels pretransplant.[14] It is given as a rapid intravenous injection in a 21-day cycle. Each cycle consists of four doses, and two to six cycles are usually required. It is metabolized by the liver. The development of thrombocytopenia and peripheral neuropathy limits its use. Gastrointestinal symptoms are common. Herpes zoster prophylaxis is required.

Eculizumab

Eculizumab was originally approved for paroxysmal nocturnal hemoglobinuria. It is a humanized mAb directed against complement protein C5, preventing cleavage into C5a and C5b. Blocking the formation of C5b inhibits the subsequent formation of terminal complex C5b-9 or membrane attack complex (MAC). Later it was used for the treatment and prevention of atypical hemolytic uremic syndrome.[15] Because of cost, its use in antibody-mediated rejection is usually as a rescue therapy for fresh allografts failing other treatments for rejection. It prevents antibody-dependent complement-mediated cytotoxicity that occurs before the antibody clearance is complete by other agents. It is also used for prevention of antibody mediated rejection in crossmatch-positive transplants and catastrophic antiphospholipid syndrome. Eculizumab is associated with an increased incidence of meningococcal infections. Patients should receive the meningococcal vaccine before therapy as well as antibiotic prophylaxis.

CHAPTER 102

Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

William R. Mulley and John Kanellis

Renal transplantation provides superior long-term outcomes compared with dialysis, in both quantity and quality of life, although the benefit gained varies among individuals.[1] The improvement in outcomes coupled with the shortage of available organs has led to an expansion of donor criteria and an increasing tendency for centers to accept marginal donor kidneys.[2] In this chapter, we review current recommendations for the evaluation and preoperative management of both the kidney transplant donor and the recipient.

RECIPIENT EVALUATION

Many units now accept patients who were previously excluded from transplantation, such as those with human immunodeficiency virus (HIV) infection, obesity, and diabetes. This is because of the availability of newer treatment options for some conditions and a greater understanding of the impact of these conditions on patient and graft survival along with changing societal attitudes regarding equality of access to transplantation. Some absolute contraindications to transplantation remain (Table 102-1), including significant current infection or malignant disease, noncompliance or substance abuse, and any condition likely to severely limit life expectancy (<1 to 2 years).[3-5]

Whereas the application of guidelines for transplant suitability may be relatively straightforward for patients with a single comorbidity, it is not as simple for those with multiple medical conditions, who represent a growing group of potential transplant recipients. Determination of suitability in such patients often requires input from specialists in a variety of medical and surgical disciplines along with allied health professionals. The final decision needs to be a joint one between clinician and patient after full and open discussion of the likely risks and benefits followed by regular reassessment of suitability while the patient awaits transplantation.

A summary of guidelines published by national and international transplantation associations[3-5] is presented in Box 102-1. Some of the important areas to consider in evaluating the transplant recipient are discussed here.

Cardiovascular Disease

Cardiovascular disease is a significant problem in patients with end-stage renal disease (ESRD) and a major cause of death in transplant recipients. Hence, cardiovascular evaluation is critical in the evaluation of the transplant recipient.

Coronary Heart Disease and Left Ventricular Dysfunction

Chronic kidney disease (CKD) itself is a major risk factor for coronary heart disease. However, the vascular lesion, clinical features, and response to treatment may be quite different in patients with ESRD compared with the normal population. The role of pretransplantation screening and intervention for coronary heart disease is controversial, making definite recommendations difficult. However, given the high incidence of cardiac events in the peritransplantation period and its major contribution to post-transplantation mortality, we favor aggressive screening and intervention in at-risk patients while avoiding unnecessary tests and procedures in low-risk candidates. Patients may be stratified into risk groups on the basis of history and examination, resting electrocardiography, and chest radiography. Further screening is unnecessary in asymptomatic patients without risk factors because of a very low incidence of coronary events.[6] Further investigation is recommended, however, in patients with abnormal test results or significant risk factors, such as previous cardiac ischemic events, diabetes, smoking, age older than 50 years, hypertension, prolonged dialysis duration (>2 years), or a family history of coronary heart disease.[3-5]

Symptomatic patients should proceed directly to coronary angiography; noninvasive functional testing should be used to screen for the need for angiography in asymptomatic patients.[7] Exercise echocardiography or myocardial perfusion scintigraphy is preferred; however, pharmacologically driven testing may be necessary if exercise is not possible. Whereas a normal result does not exclude coronary heart disease, both testing modalities have negative predictive values for myocardial infarction or cardiac death in excess of 96% in patients with renal failure.[8] If significant coronary heart disease is identified, treatment before transplantation should be instituted. Treatment consists of medical management including aggressive risk factor modification, angioplasty and stenting or coronary artery bypass grafting in patients with significant stenoses.[7] A suggested approach is presented in Figure 102-1.

In patients with clinical or radiologic evidence of left ventricular dysfunction, transthoracic echocardiography should be performed to assess the severity and nature of the dysfunction. A cause should be sought and treated when possible. Severe left ventricular dysfunction may improve significantly after transplantation; therefore it is not in itself an absolute contraindication to transplantation. It is, however, associated with reduced post-transplantation survival; thus in patients with significant comorbidities it does represent a contraindication to transplantation unless, in rare instances, combined heart and kidney transplantation is appropriate.[3-5]

Cerebrovascular Disease

Patients with a history of recent transient ischemic attack or stroke are at greatest risk of recurrence early after the primary event; and because stroke after transplantation is associated with a high rate of mortality,[9] a waiting time of 6 months is recommended. Meanwhile, aggressive risk factor modification should be undertaken to limit the likelihood of further stroke. Routine screening for cerebrovascular

Contraindications to Renal Transplantation

Current Absolute Contraindications to Transplantation	Previous Contraindications to Transplantation*
Active sepsis	HIV infection
Current uncontrolled malignant disease	Hepatitis B and C
Uncontrolled psychosis	Obesity
Active drug dependence	Mood disorders
Any medical condition with a severely shortened life expectancy (<1-2 years)	Age above 60 years
Positive T cell CDC crossmatch	Previous malignant disease
	Blood group incompatibility

Table 102-1 Contraindications to renal transplantation. *CDC,* Complement-dependent cytotoxicity; *HIV,* human immunodeficiency virus. *These conditions are now acceptable under certain circumstances—see text.

Recipient Evaluation Checklist

History and Examination
- Cause of renal failure and risk of recurrence
- Sensitization (transfusion, pregnancy, previous transplant)
- Past and current infections (TB, hepatitis, HIV)
- Immunization (especially hepatitis B)
- Malignancy
- Cardiovascular risks (smoking, hypertension, diabetes)
- Pulmonary, gastrointestinal disease
- Genitourinary tract
- Psychiatric, psychological history
- Surgical issues (weight, iliac vessels, abdomen, previous surgery)

Laboratory and Radiologic Investigations
- Viral serology (HIV, CMV, EBV, hepatitis B and C)
- Liver function tests
- Bone-related issues (PTH, calcium, phosphate)
- Chest radiograph
- Electrocardiogram
- Prostate-specific antigen (for men older than 50 to 60 years)
- Mammogram or breast ultrasound (women older than 50 years or with family history of breast cancer)
- Pap smear (sexually active women)

Immunologic Investigations
- ABO blood group and HLA typing
- Screening for HLA antibodies and autoreactive antibodies
- Crossmatching

Box 102-1 Recipient evaluation. *CMV,* Cytomegalovirus; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HLA,* human leukocyte antigen; *PTH,* parathyroid hormone; *TB,* tuberculosis.

disease is not advocated in asymptomatic patients. Evidence suggests a benefit in further investigation of patients with a carotid bruit and treatment with carotid endarterectomy if a significant stenosis is found.[10] Patients with polycystic kidney disease at high risk of cerebral aneurysm rupture, such as those with a previous personal or family history of cerebral hemorrhage, should be screened for cerebral aneurysm before transplantation; however, there is no conclusive evidence to support doing so in those without such risk factors. Risk of cerebral aneurysm in polycystic kidney disease is discussed further in Chapter 46.

Assessment and Management of Cardiac Status in Potential Transplant Recipients

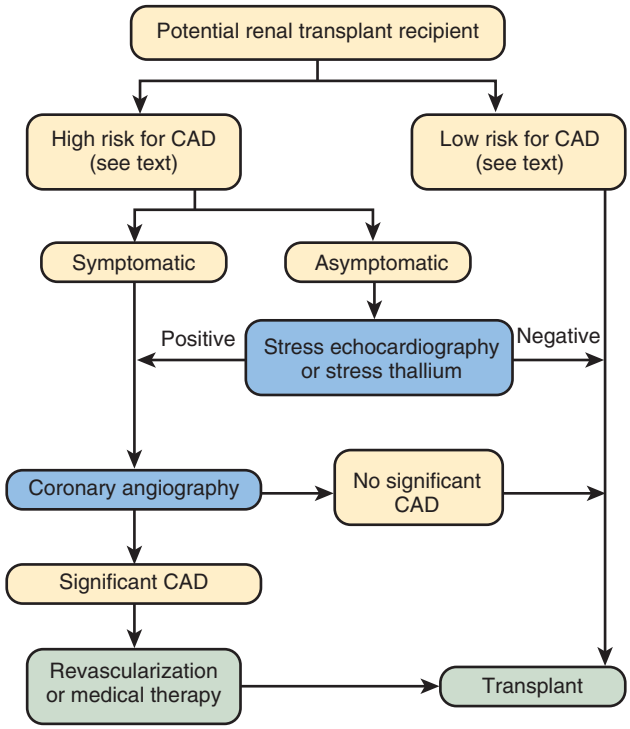

Figure 102-1 Assessment and management of coronary artery disease in potential transplant recipients. *CAD,* Coronary artery disease.

Peripheral Vascular Disease

Asymptomatic patients with strong femoral and peripheral pulses generally require no further investigation. Patients with diabetes, history of claudication, or reduced pulses require vascular imaging beginning with Doppler ultrasound. Significant disease involving the iliac vessels may make transplantation difficult or impossible and may worsen ischemia in the distal leg. Although it is not an absolute contraindication to transplantation, peripheral vascular disease is associated with increased mortality[11] and should be considered in conjunction with the patient's other comorbidities.

Cancer

Cancer is a major cause of death in renal transplant recipients. Further increases in the incidence of malignant disease are likely with increased graft survival and acceptance of older recipients. The incidence of malignant disease is also increased in transplant recipients compared with the general population.[12] However, the effect of transplantation on different types of cancers is not uniform, nor is the effect of different immunosuppressive agents.[13] Some cancers, such as nonmelanoma skin cancers (61% to 82% at 20 years) and lymphoma, have a markedly increased incidence in transplant recipients compared with the general population; the incidence of other malignant neoplasms, such as breast and prostate, is not as markedly increased.[14] In patients with a previous malignant neoplasm, guidelines have been devised on the basis of the likelihood of recurrence after transplantation (Box 102-2). In general, the longer the cancer-free interval before transplantation, the smaller the recurrence risk. For most malignant neoplasms, a period of 2 to 5 years

Guidelines for Transplantation in Patients with Previous Malignancies

Usual Waiting Time of 2 Years
- Most cancers

No Waiting Time Necessary
- Incidental renal carcinoma
- *In situ* carcinoma
- Focal neoplasm (defined as a localized tumor without metastases)
- Low-grade bladder cancer
- Basal cell skin cancer

Waiting Time of More Than 2 Years May Be Necessary
- Melanoma
- Breast cancer
- Colorectal cancer
- Uterine cancer

Box 102-2 Guidelines for transplantation in patients with previous malignant disease.[65]

is recommended.[3-5] There are several exceptions. A longer waiting time (≥5 years) is recommended for breast cancer with nodal involvement, melanoma, and colorectal cancer worse than Dukes stage B1; no waiting time is thought necessary for nonmelanocytic skin cancers confined to the skin, *in situ* cancers of bladder and cervix, focal microscopic low-grade prostate cancer, and small (<7 cm) incidentally discovered and surgically removed renal cell carcinomas. Given the heterogeneity of malignant neoplasms, waiting periods before transplantation need to be individualized, taking into account the patient's other comorbidities.

Although extensive screening of all potential recipients is not warranted, guidelines appropriate for the general population should be adopted in screening for breast, cervical, prostate, and colorectal cancer. Chest radiography is performed as part of the routine assessment. More comprehensive and targeted evaluation is recommended in patients with a strong family history or suggestive clinical features of malignant disease or conditions associated with an increased risk of malignant disease, such as renal imaging in patients with acquired cystic disease of the kidney for possible renal cell carcinoma.[3,4]

Infectious Complications

All patients are screened for previous exposure to Epstein-Barr virus and cytomegalovirus (CMV) to assess the risk of infection, either primary or reactivation. This guides the appropriate use of prophylactic antiviral agents. For example, patients who are negative for CMV IgG who receive a kidney from a CMV-positive donor are at the highest risk of infection and may benefit from prolonged prophylaxis compared with the lower-risk CMV-negative donor to a CMV-negative recipient (see Chapter 105). Screening for other infections should be tailored to geographic location; a guide for screening is presented in Table 102-2. Immunization against hepatitis B should be undertaken in all potential recipients. Immunization against encapsulated organisms (pneumococci, *Haemophilus influenzae,* and meningococci) should also be considered in patients at high risk of antibody-mediated rejection in case rescue therapy—for example, splenectomy or complement inhibition with eculizumab—is required.

Before highly active antiretroviral therapy (HAART), HIV infection was considered an absolute contraindication to transplantation because of very poor patient survival.[15] In the HAART era, HIV infection is seen as a manageable chronic disease, and transplantation is offered to HIV-positive patients at many centers that have experience in managing HIV infection and transplantation. Reports of short- to medium-term results suggest excellent patient and graft survival in carefully selected recipients.[16] Longer-term studies are under way to further explore these outcomes. Patients with sustained CD4 counts above 200/ml and undetectable HIV viral loads, without an acquired immunodeficiency syndrome (AIDS)–defining illness, can be considered for transplantation. Patients with hepatitis B may be considered for renal transplantation if there is no evidence of active viral replication (hepatitis B virus [HBV] DNA or hepatitis B early antigen [HBeAg] positive), advanced liver disease or cirrhosis (as determined by liver biopsy), or hepatocellular carcinoma.[3-5] Immunosuppression can increase HBV replication; hence, treatment before transplantation is indicated in patients with active disease, and although data to support prophylactic antiviral therapy, such as entecavir, after transplantation are scarce, it is commonly practiced while immunosuppression is at its highest (initial 12 to 24 months). Early reports suggest that mortality may be increased in HBV-positive patients after transplantation compared with HBV-negative recipients.[17] The significance of these findings is unclear in the current era with more effective treatment options and if only patients with inactive disease undergo transplantation. Frank disclosure of possible risks involved is recommended.[3-5]

Patients with hepatitis C should be assessed by measurement of hepatitis C virus (HCV) viral load and a liver biopsy. Treatment should be instituted before transplantation; however, candidates who do not clear the virus may still proceed with transplantation because mortality in this group is improved compared with those remaining on dialysis.[18] HCV-positive patients may in some units, with informed consent, receive a kidney from an HCV-positive donor. Any possible increased risk may be offset by a significantly reduced waiting time. Patients with hepatitis B and C should be screened every 12 months for hepatocellular carcinoma by liver ultrasound and serum alpha fetoprotein. Those with cirrhosis may be considered for combined kidney-liver transplantation.

Patients at high risk of tuberculosis reactivation after transplantation (previous tuberculosis, abnormal chest radiograph, or positive tuberculin skin test result; residence in an endemic area) who have not been previously treated should receive prophylactic isoniazid after transplantation (see Chapter 105). Recently, interferon-γ (IFN-γ) ELISPOT assays have been proposed to replace or supplement the tuberculin skin test because they appear more sensitive for detecting latent tuberculosis infection.[19] The need to screen patients is determined by the likelihood of previous exposure.

Screening Tests for Occult Infection

Routine Serology	Where Indicated, Tests for the Following Conditions and Infections	Other Routine Investigations
Cytomegalovirus Epstein-Barr virus Hepatitis B virus Hepatitis C virus HIV	HTLV Human herpesvirus 8 Malaria Schistosomiasis *Strongyloides stercoralis* *Trypanosoma cruzi* Tuberculosis	Chest radiograph Urine culture

Table 102-2 Screening tests for occult infection. Routine screening tests for occult infection. *HIV,* Human immunodeficiency virus; *HTLV,* human T-lymphotropic virus.

Previous graft loss caused by polyoma (BK) viral nephropathy is not a contraindication to repeated transplantation. Waiting for serum and urine BK polymerase chain reaction test results to become negative appears to be preferable,[20] whereas the value of graft nephrectomy before repeated transplantation is unclear. Vigilant screening for recurrence is recommended.[5]

Obesity

Transplantation in obese patients (body mass index [BMI] >30 kg/m^2) generally improves survival compared with matched waiting list controls, but inferior outcomes for patient and graft survival, delayed graft function and wound healing, and infective complications have been reported in obese compared with nonobese patients, particularly those with a BMI above 36 kg/m^2.[21] There are several reports to the contrary, however, including a recent multivariate analysis of registry data suggesting that obesity is not associated with worse graft and patient survival when comorbidities are controlled for.[22] Nevertheless, the overweight or obese patient is more likely to develop new-onset diabetes after transplantation, which can adversely affect graft and patient survival. Potential transplant recipients with obesity should be advised to lose weight as a means to decrease this risk before transplantation.

Recurrent Disease

The risk of disease recurrence needs to be discussed as part of the informed consent process, particularly in certain primary renal diseases (e.g., focal segmental glomerulosclerosis). Graft loss attributed to recurrent disease has increased in recent years but still accounts for only 5% of graft loss.[23] The risks and management of recurrent disease are discussed in Chapter 108.

Gastrointestinal Disease

Screening for gastrointestinal disease is not warranted in the asymptomatic patient.[4,5] Patients with active acute or chronic pancreatitis should not undergo transplantation until they have been clear of symptoms for 12 months. Patients with active peptic ulcer disease should be treated before transplantation with proton pump inhibitors, and this should be continued to prevent ulceration after transplantation. Patients with symptomatic diverticular disease require colonoscopy and potential colonic resection in severe cases before transplantation because they are at increased risk of perforation on immunosuppressive medications.[4] Whereas symptomatic cholecystitis should be treated surgically before transplantation, asymptomatic cholelithiasis does not require surgery before transplantation because cholecystectomy after transplantation is required in less than 10% of these patients and results in no increased mortality or morbidity compared with pretransplantation cholecystectomy and no deleterious effects on graft function.[24]

Genitourinary Disorders

Screening for genitourinary disorders before transplantation is indicated in those with a history or renal ultrasound suggestive of urinary obstruction, especially in children, in whom urologic problems are a major cause of ESRD. If obstruction is found, urologic assessment, which may include voiding cystourethrography and urodynamic studies, is indicated to determine the best course of action to ensure bladder emptying and limit bladder pressures after transplantation; this may involve bladder augmentation, urinary diversion, or self-catheterization.

Native nephrectomy before transplantation should be considered for recurrent or persistent renal sepsis, particularly in the setting of nephrolithiasis. Very large polycystic kidneys may need to be removed to accommodate the transplant kidney. Whether previous grafts should be removed before repeated transplantation is controversial. Nephrectomy of a failed graft is commonly performed on withdrawal of immunosuppression in patients with early graft failure (<12 months)[25] to alleviate symptoms such as pain over the graft, fever, and weight loss.[26] Other indications include graft sepsis and allowance of room for the new graft. However, unless there is a convincing reason to remove the graft, it is generally left *in situ*. In these circumstances the patient may need to stay on minimal immunosuppression (e.g., prednisolone, 5 mg/day) for 3 to 6 months to minimize graft tenderness and inflammation. Graft nephrectomy may be associated with an increased risk of human leukocyte antigen (HLA) sensitization,[25] perhaps relating to loss of antigen-dependent tolerogenic mechanisms[27]; this, however, is not a universal finding. Another advantage of leaving the previous transplant *in situ* is preservation of any residual renal function and urine output.

Pulmonary Disease

Initial assessment by physical examination and chest radiography is indicated for all potential recipients; further testing, such as pulmonary function tests or computed tomographic scanning, is performed if it is clinically indicated. Recent guidelines suggest that patients with a short life expectancy associated with pulmonary disease, such as cor pulmonale, uncontrolled asthma, and severe obstructive lung disease (FEV_1 <25% of predicted or P_{O_2} <60 mm Hg [8 kPa] on room air), or those needing home oxygen should be excluded from transplantation.[5] Many units require patients to cease smoking before acceptance because smokers have an increased risk of death and graft loss. Cessation of smoking demonstrates positive lifestyle behavior and good compliance, suggesting that these factors will be optimized in the post-transplantation period.

Psychosocial Issues

Psychosocial issues can have a major impact on transplant outcomes. Patients should be evaluated by a health professional experienced in judging capacity to consent and assessing likely compliance with a transplant medication regimen. Compliance with the post-transplantation treatment regimen is vital to minimize premature graft loss. Predicting compliance can be challenging and may be based on pretransplantation compliance, such as adherence to dialysis management regimens. If compliance is unlikely, as judged by medical, psychiatric, psychological, and social work assessment, transplantation should not proceed.[3-5]

Cognitive impairment is not an absolute contraindication to transplantation as long as appropriate supports and proxy arrangements are in place. Patients with psychiatric illnesses including depression, bipolar affective disorder, and psychosis require assessment by a psychiatrist to determine transplant suitability and to devise a management plan to cope with possible consequences of immunosuppressive medications such as corticosteroids.[3-5] Drug and alcohol addiction should be addressed with rehabilitation and demonstrated abstinence before the patient is listed for transplantation.

Presence of Multiple Comorbidities

Increasingly patients with multiple comorbidities are referred for consideration of transplantation as the boundaries for acceptance onto transplant programs broaden. Each problem in itself is often

Reevaluation of Suitability for Transplantation		
Cardiac reevaluation every 1-2 yr depending on risk factors (e.g., diabetes)	**Cancer surveillance relevant to age, sex, and risk factors**	**Comorbidity reassessment**
Stress echocardiogram or thallium scan Angiography if indicated (see Fig. 102-1)	Prostate-specific antigen Mammography Pap smear Colonoscopy if indicated Skin cancer check	Viral hepatitis Liver function tests Alpha fetoprotein Liver ultrasound HIV CD4 count ? AIDS-defining illness Other (see discussion of individual organ systems)

Table 102-3 Reevaluation of suitability for transplantation. *AIDS,* Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

not an absolute contraindication; however, taken together they may mean the patient has significantly reduced overall survival prospects. Controversially, some societies have suggested that patients must have specified long-term survival prospects—for example, an 80% chance of surviving 5 years—to be accepted for transplantation from a deceased donor. In addition, risk calculators have been devised based on registry data to allow such predictions.[28]

Reevaluation of Patients on the Waiting List

Patients may wait several years on the transplant list before receiving an opportunity to undergo transplantation. It is vital that when their opportunity comes, they are still suitable. A targeted reassessment of waiting-list patients therefore should be conducted at regular intervals (Table 102-3). General measures, such as cancer screening (e.g., skin, prostate, breast, and cervical), should be continued on a regular basis as indicated. Reassessment of cardiac status is advocated on the basis of risk. Diabetic and other high-risk patients should be reassessed every 1 to 2 years.[7] The value of reassessing low-risk patients is more questionable, but given that CKD is a strong risk factor for cardiac disease, repeated stress testing by exercise or pharmacologically driven echocardiography or myocardial perfusion scintigraphy at least every 3 years seems appropriate. Patients with preexisting medical conditions (e.g., HIV infection and viral hepatitis) require regular specialist reviews, with any issues arising brought to the attention of the transplant team. Surgical reassessment may be needed in patients with peripheral vascular disease, if patients gain weight, or if a complication such as peritonitis occurs while the patient awaits transplantation. Patients should be temporarily removed from the waiting list if they develop a serious infection or other illness until it is resolved.

DONOR EVALUATION

Donor kidneys can be obtained from both deceased and living donors.

Deceased Donors

Classification of the Deceased Donor

Deceased donors can be classified as either heart-beating donors with loss of brainstem function (donation after brain death [DBD]) or non–heart-beating donors (donation after cardiac death [DCD]).

Classification of DCD Donors
As per Maastricht classification (Kootstra, 2007) (also known as non–heart–beating donors)
Uncontrolled
Category I: Dead on arrival to hospital
Cause of death is usually obvious (e.g., severe head injury) and no resuscitation is given.
Category II: Unsuccessful resuscitation
The patient is brought to the emergency department while being resuscitated, but this is not effective. Alternatively, arrest occurs in hospital and patient is unable to be resuscitated.
Controlled
Category III: Awaiting cardiac arrest
Severe brain injury without brain death. Patients are usually ventilator dependent. Arrest occurs once support is withdrawn.
Category IV: Cardiac arrest while brain dead
Patient suffers cardiac arrest after being declared brain dead. Alternatively, this occurs during brain death testing and the patient is not or cannot be successfully resuscitated.
Category V: Unexpected cardiac arrest in a critically ill patient
Example: Unsuccessful resuscitation after unexpected cardiac arrest in intensive care.

Box 102-3 Classification of donation after cardiac death (DCD) donors.[29]

In recent years the proportion of DCD donors has been increasing in many countries as a result of policies aiming to maximize the opportunities for donation.

Donation after brain death donors can be further divided into standard criteria donors and extended-criteria donors. The definition of extended-criteria donor varies; in the United States it refers to heart-beating donors older than 60 years or 50 to 59 years old with two or three of the following criteria: a history of hypertension; elevated serum creatinine at donation (>1.5 mg/dl or 130 µmol/l); or death from a cerebrovascular accident. In some jurisdictions, the term *marginal donor* is loosely used to describe donors who are less than optimal for some reason—usually the presence of significant underlying disease (hypertension, diabetes, vascular disease, renal impairment) or advanced age (older than 65 years).

Donation after cardiac death can occur by several mechanisms. The Maastricht classification separates these types of donors into controlled and uncontrolled categories (Box 102-3).[29] Controlled donors are those who suffer cardiac arrest after withdrawal of support or after brain death. Uncontrolled donors are those who are deceased on arrival to the hospital or who have a failed cardiopulmonary resuscitation. From a practical point of view, a system that uses controlled donors is easier to implement than one using uncontrolled donors. This is largely related to factors surrounding ethical considerations and the consent process involving relatives of the donor.

The survival of kidneys from extended-criteria donors and from some categories of DCD donors is generally inferior to that of kidneys retrieved from standard criteria donors.[30,31] Many matching schemes attempt to allocate these less ideal grafts to recipients who are predicted to have a lower-than-average overall survival, but practice varies considerably among countries with regard to these issues.

Evaluation of the Deceased Donor

In most circumstances, organ donor coordinators screen potential deceased donors after referral from hospital intensive care units or emergency departments. Patient records are assessed and relatives

are interviewed about important aspects of the clinical history. The assessment focuses on general health (including history of infections and cancer), social history (especially drug use and sexual history), and laboratory evidence of renal impairment or other diseases (Box 102-4). Patients with sepsis, acute hepatitis, or HIV infection are excluded from donation, as are those with a history of malignant disease. Nonmelanoma skin cancers do not lead to exclusion, nor do primary brain tumors unless they are of a high grade or the donor has received chemotherapy or had a craniotomy or cerebral shunt inserted.[32] In some centers, donors potentially carrying HBV or HCV are accepted only for recipients positive for these viruses. The risk of an unknown donor malignant neoplasm is approximately 1.3%; however, the risk of transmitting a donor malignant neoplasm is lower at approximately 0.2%.[33]

Evaluation of renal function is determined by history, urinalysis, and serum creatinine concentration. In some patients a biopsy (often performed at retrieval) may provide useful information, particularly with extended-criteria donors.[34] Serum creatinine concentration at admission should be in the near-normal range (estimated glomerular filtration rate [eGFR] >60 ml/min), but a temporary decline in renal function is acceptable if the function is expected to recover. Proteinuria (>0.5 g/24 h) may indicate structural renal damage and is a valid reason for nonacceptance.

The use of kidneys from very small donors varies among centers. Donors younger than 5 or 6 years are generally associated with high risk of failure, especially from vascular thrombosis.[35] For this reason, some centers occasionally transplant two kidneys—transplanted *en bloc,* using the aorta and inferior vena cava as conduits.[36]

Deceased Donor Evaluation Checklist

Medical History
- Hypertension, diabetes
- Malignant disease
- Infections: past and current (TB, hepatitis, HIV)
- Transfusions
- Trauma
- Surgical history
- Hospitalizations

Social History
- Intravenous drug use
- Alcohol, smoking
- Sexual behavior
- Tattoos, acupuncture
- Overseas travel
- Incarceration

Examination
- Blood pressure
- Cardiac, vascular
- Lymphadenopathy
- Abdominal

Laboratory and Technical
- Serum creatinine
- Urinalysis, urine culture
- Liver function tests
- Coagulation profile, complete blood count
- Blood culture
- *Virology, depending on geographic region: antibodies to CMV, EBV, HSV-1 and HSV-2; HHV-6, HHV-7, HHV-8; HCV, HBV (including HBsAg, anti-HBcAg, IgG and IgM), HIV, West Nile virus, rabies, HTLV-1
- Parasites, depending on geographic region: malaria, babesiosis, toxoplasmosis, Chagas disease, syphilis
- Fungi in appropriate regions: *Coccidioides, Histoplasma*
- Tuberculosis (depending on geographic region)
- Chest radiograph
- Electrocardiogram
- Biopsy if there is concern for chronic kidney disease

Operating Room Evaluation
- Intra-abdominal examination to detect occult malignant diseases
- Macroscopic appearance of kidneys

Deceased Donor Management Before Transplantation

In the brain-dead donor, maintenance of adequate blood pressure and oxygenation are important to prevent warm ischemic renal injury. The use of pressor agents, volume resuscitation, and other conditioning strategies is complex and has been the subject of several guideline documents (see the Intensive Care Society website, www.ics.ac.uk). In this category of donor, the kidneys are generally not subject to significant warm ischemia at the time of organ retrieval unless the donor suffers prolonged hemodynamic compromise.

In DCD, once death is certified and deemed irreversible, either rapid surgical exposure of the great vessels with cooling of the organs followed by prompt retrieval is required, or, alternatively, the kidneys are cooled *in situ* by insertion of perfusion catheters through the femoral vessels (see also Chapter 103). Surgical retrieval can then take place after a period of delay to variably allow one or more of the following: family counseling, donor assessment, or relocation from one hospital area to another (e.g., from the intensive care unit or emergency department to the operating theater). DCD is inevitably associated with warm ischemic renal injury. This is responsible for the higher rate of delayed graft function that is seen in this group. The need for dialysis support after transplantation is approximately 50% but varies from 30% to 90%, depending on the Maastricht category of donor.[29]

Living Donors

Live kidney donation is currently accepted in most countries on the basis of the demand for deceased donor organs—which far outweighs the supply—as well as the apparent very low level of risk to the majority of healthy donors.[37] Added to this are the detrimental effects for the recipient of waiting on dialysis and the excellent, generally superior results obtained through use of living donors.

Living donors may be related, unrelated, altruistic, or part of a donor exchange or list-exchange program. In many countries with well-established transplant programs, half or more of all transplants are now performed with living donors. In Japan, Brazil, and the Middle East, more than 80% of transplants use living donors. The superior outcomes of transplantation from living donors compared with that from deceased donors has supported the development of living donor paired exchange and living donor–deceased donor exchange.[38] In the first instance, living donors who are incompatible with their intended recipients are exchanged between recipients. In

the other instance, the donor donates to the wait list in exchange for the intended recipient's receiving priority on the list.[39]

In some countries, either a state-organized or a free-market system results in the purchase of living donor kidneys; this is a highly controversial area.[40] The Declaration of Istanbul on organ trafficking and transplant tourism and the World Health Organization both condemn the exploitation of living donors who are thought to be vulnerable (illiterate, impoverished, undocumented immigrants, prisoners, and political or economic refugees).[41]

In recent times, many units have extended their selection of donors to include patients who are mildly hypertensive, overweight, or hyperlipidemic or who have other abnormalities (such as isolated microhematuria or previous stone disease).[42] Whereas donation appears to be safe in the short to medium term for most of these patients, adequate studies have not been performed to assess the longer-term medical or psychological effects.

Mortality and Morbidity

Mortality related to living donation is a catastrophic and unexpected event. Registry data and institutional surveys suggest the perioperative risk of donor death is approximately 3 in 10,000.[43] Donor mortality and major complications appear equivalent with laparoscopic and open donor nephrectomy. In open surgery, the risks are related to perioperative complications, including pulmonary emboli, pneumonia, and ischemic events. With laparoscopic surgery, complications are largely a result of catastrophic intraoperative events or postoperative bleeding related to securing of the vascular pedicle.[43,44]

In the longer term, survival of donors appears to be similar to that of controls in the general population (Fig. 102-2).

Numerous series report early operative complications after laparoscopic and open donor nephrectomy with rates of 3% to 38%.43 These reports variably include events such as bleeding, wound infection, urinary retention, pneumonia, asymptomatic and symptomatic pneumothorax, ileus, and need for transfusion, among other things. This enormous variability relates to both definition of complication and accuracy of reporting.

Case series report that physical and psychological function in living donors is higher than the community norm. Physical issues reported by donors after donation frequently include a temporary decrease from baseline in energy; some note a longer time to full recovery than anticipated and incision pain (after open nephrectomy) that lasts longer than expected. Psychological factors usually include an improved relationship with the recipient, an improved self-image, and frequently a positive effect on the donor's life. Longer-term psychological morbidity appears minimal; however, some series have reported an association with anxiety, depression, or other psychological issues in a small proportion of the patients.[45,46] Even though most donors have a positive experience, a small number for a variety of reasons do regret the decision to donate (0% to 5%). Psychological evaluation before donation is therefore extremely important, as is the need to provide support and counseling after donation. This issue is particularly important when the transplant does not go as well as anticipated.

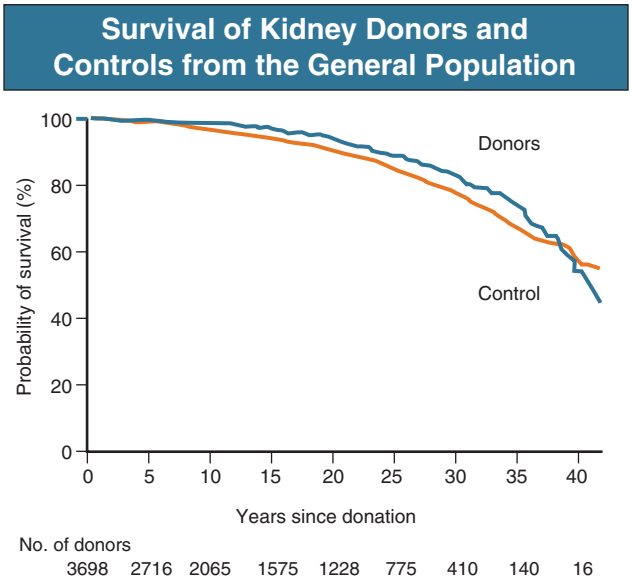

Figure 102-2 Survival of living kidney donors. The survival of living related donors is similar to the expected survival derived from the general population. Error bars at 5-year intervals indicate 95% confidence intervals for the probability of survival among kidney donors. *(Modified with permission from reference 37.)*

Evaluation of the Living Donor

Several groups have developed guidelines for the evaluation of the living donor, including the Amsterdam forum[47] and consensus guidelines published by several U.S. transplant centers.[48] An outline of the usual donor evaluation is shown in Boxes 102-5 and 102-6. It includes a thorough history and examination, blood and urine screening tests, chest radiography, electrocardiography, age- and family history–appropriate cardiac stress test, and radiographic

Living Donor Evaluation Checklist: History and Examination

History
- Hypertension
- Diabetes (including gestational)
- Infections
- Cancer (including skin lesions)
- Vascular disease
- Renal calculi
- Gout
- Urinary tract
- Family history
- Medications (including NSAIDs, herbs)
- Smoking
- Illicit and intravenous drug use
- Sexual history
- Vocation, sport interests
- Level of physical activity, exercise
- Psychiatric history, psychological factors
- Willingness to donate
- Relationship with recipient

Examination
- Blood pressure
- Weight and height, BMI
- Joints, skin
- Cancer (including skin lesions, breast)
- Lymph nodes
- Vascular disease
- Heart and lungs
- Abdomen

Living Donor Evaluation Checklist: Investigations

Laboratory and Radiologic Investigations

- Urinalysis (blood, protein)
- Urine microscopy and culture (blood, organisms)
- Serum electrolytes, urea, and creatinine
- Liver function tests
- Full blood examination
- Fasting blood glucose and/or oral glucose tolerance test
- Fasting lipids
- 24-hour urine, creatinine clearance or GFR measurement by iothalamate, Cr-EDTA, DTPA clearance, 24-hour urine protein, or protein excretion by other methods (e.g., protein-creatinine ratio)
- Serum uric acid, calcium, phosphate
- Viral screening: HBV, HCV, HIV, CMV, EBV serology
- Syphilis screening (RPR)
- TB screening (PPD)
- Electrocardiogram
- Chest radiograph
- Females: Pap smear, mammography (according to age and family history)
- Males: prostate-specific antigen (according to age and family history)
- Additional cardiac investigations (where indicated by age, history, risk factors)
- Stress test
- Echocardiography
- Ambulatory blood pressure

Renal Imaging (According to Local Expertise)

- Computed tomographic angiography
- Magnetic resonance imaging angiography
- Catheter angiography

Box 102-6 Living donor evaluation checklist: investigations. *CMV,* Cytomegalovirus; *Cr-EDTA,* chromium-labeled ethylenediaminetetraacetic acid; *DTPA,* diethylenetriaminepentaacetic acid; *EBV,* Epstein-Barr virus; *GFR,* glomerular filtration rate; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PPD,* purified protein derivative test; *RPR,* rapid plasmin reagent; *TB,* tuberculosis.

Acceptable GFR in Living Donors by Age

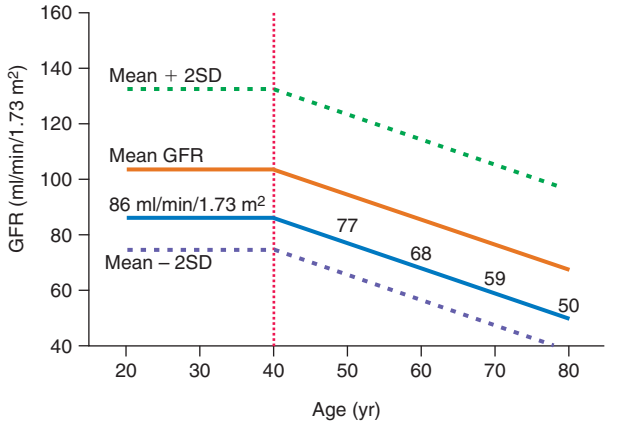

Figure 102-3 Acceptable glomerular filtration rate *(GFR)* in living donors by age. Diagram explaining the minimum acceptable age-associated GFR in living donor candidates. The *solid orange line* shows the variation with age of mean GFR. The *outer dashed lines* show the +2 and –2 population standard deviation (SD) limits. GFR is constant up to the age of 40 years and then declines at the rate of 9 ml/min/1.73 m^2 per decade. The reference plot is based on an analysis of data for 428 living renal transplant donors who had chromium 51–labeled ethylenediaminetetraacetic acid (^{51}Cr- EDTA) GFR measurements. The *solid blue line* shows the acceptable lowest GFR for young adults of 86 ml/min/1.73 m^2, declining to 50 ml/min/1.73 m^2 at age 80 years. For transplant donors with preoperative GFR values above the solid blue line, the GFR of the remaining kidney will still be above 37.5 ml/min/1.73 m^2 at age 80 years. *(Modified with permission from the revised British Transplantation Society/Renal Association U.K. guidelines for living donor kidney transplantation, available at www.bts.org.uk/.)*

assessment of the kidneys and vessels. An assessment of the anatomy may be achieved by computed tomographic angiography or magnetic resonance angiography, depending on the particular center. Formal renal arteriography, although informative, is no longer necessary, given the anatomic detail obtainable noninvasively with modern radiologic techniques.

Assessment of Renal Function

Most centers use a glomerular filtration rate (GFR) of 80 ml/min/1.73 m^2 as the lower limit for donors. It is accepted that this is an overgeneralization, potentially representing too low a limit for the younger donor (e.g., younger than 40 years) and too high a limit for the older donor (e.g., older than 60 to 65 years). For this reason, an alternative approach is to consider the age-specific GFR and to accept donors only if they fall within the average for this figure. This method has been recommended by the British Transplantation Society (guidelines available at www.bts.org.uk) and is presented in Figure 102-3. An alternative approach uses the life expectancy of the donor.[49] By use of these calculations, a 30-year-old donor would require a GFR of 123 ml/min/1.73 m^2; the required GFR for a 70-year-old would be approximately 68 ml/min/1.73 m^2.

Hypertension and Proteinuria in the Living Donor

Donation may be acceptable for some hypertensive individuals if blood pressure is well controlled, GFR is as expected for donation and age, and there are no features of end-organ involvement from hypertension.[47,48] The evaluation for hypertension should include blood pressure measurements on three separate occasions. Borderline elevated levels should be further evaluated with ambulatory blood pressure monitoring. If elevated blood pressure is detected and the prospective donor is still under consideration, echocardiography (looking for left ventricular hypertrophy), ophthalmologic evaluation (looking for hypertensive retinal changes), and assessment for microalbuminuria (suggesting hypertensive renal damage) should be undertaken. The prospective donor should be excluded if any of these features are present. Guidelines typically exclude from donation those with urine protein higher than 300 mg/24 h (with or without hypertension). It is our view that the presence of microalbuminuria (with or without hypertension) should also lead to exclusion, given the likely underlying renal and systemic microvascular pathology this signifies, particularly in those with other cardiovascular risk factors.

Obesity and Abnormal Glucose Tolerance in the Living Donor

Although many centers accept obese living donors, several issues need to be addressed. These include the impact of obesity on perioperative complications, future renal function, and cardiovascular health. In one study, obese (BMI >30 kg/m^2) patients had an

increased rate of proteinuria and renal impairment 10 to 20 years after nephrectomy.[50] Obese individuals may therefore be more prone to development of renal disease after donation, but this issue has not been carefully studied.

Future risk of diabetes is another important consideration. In addition to close assessment of those who are overweight, prospective donors with an abnormal fasting glucose concentration, a history of gestational diabetes, or a first-degree relative with diabetes should be evaluated with an oral glucose tolerance test. An abnormal glucose tolerance test result is a contraindication to donation. Patients often lose weight and otherwise change their lifestyle (exercise, diet), leading to an improvement in their results and eventual acceptance as donors. It is important that these lifestyle and risk modifications be sustained after donation occurs.

Renal Abnormalities in the Living Donor

As well as factors identified in the history (e.g., previous calculi, urinary tract infections, prostatic disease), a variety of previously unidentified renal abnormalities can be encountered in prospective donors during their assessment. These include microhematuria, renal scarring (e.g., polar distortion suggesting reflux nephropathy), renovascular abnormalities, and renal masses and cysts.

Isolated hematuria in a prospective donor necessitates consideration of thin basement membrane nephropathy, Alport syndrome (carrier status in women may cause minor or moderate abnormalities), and IgA nephropathy as well as urinary tract infection, malignant disease, and nephrolithiasis. Microhematuria is a relatively common problem, with persistent microhematuria evident in approximately 3% of the general population.[51] Among the possible disorders, IgA nephropathy is generally a contraindication to live donation, whereas thin basement membrane nephropathy may not necessarily be so.[52] The implications of isolated mesangial IgA without other manifestations of glomerulonephritis require further study, and donation should be decided in the context of family history, absolute renal function, presence of interstitial disease, and age. If persistent isolated asymptomatic microhematuria is detected during living donor evaluation, a workup should include cystoscopy and urinary cytology if the hematuria is not clearly glomerular in origin. A renal biopsy should be considered when there is glomerular hematuria or the possibility of familial disease (e.g., Alport syndrome, IgA nephropathy) because this aids the decision-making process by clarifying the prospective donor's future risk of progressive renal disease.[53]

Those with a history of bilateral or recurrent stones and those with systemic conditions associated with recurrent stone disease should not donate. An asymptomatic potential donor with a current single stone is suitable if the donor does not have a high risk of recurrence, if the stone is smaller than 1.5 cm, and especially if the stone is potentially removable during transplantation.[47] The evaluation of an asymptomatic donor with a single prior episode of nephrolithiasis should include evaluation of serum calcium, creatinine, albumin, and parathyroid hormone levels; spot urine for cystine; urinalysis and urine culture; spiral computed tomographic scan; chemical analysis of the stone, if available; and 24-hour urine measurement of oxalate, uric acid, and creatinine.

Atherosclerotic renal vascular disease is a relative contraindication to living donation. If it is discovered, the donor should be normotensive, have normal renal function, and have only unilateral disease.[54] Careful evaluation for coronary heart disease and peripheral vascular disease should be undertaken, given the significant association of renovascular disease with atherosclerosis elsewhere. Fibromuscular dysplasia is found in 2% to 4% of prospective donors. Donors with severe and diffuse disease should not be accepted for donation. The age of the prospective donor should also be considered, with the outcome in donors older than 50 years more predictable and benign than in younger donors.[55]

Malignant Disease

A past history of certain malignant neoplasms is considered a contraindication to live kidney donation. These include melanoma, testicular cancer, renal cell carcinoma, bronchial and breast cancer, choriocarcinoma, hematologic malignant neoplasm, and multiple myeloma.[47] A history of malignant disease may be acceptable for donation if prior treatment of the malignant neoplasm does not decrease renal reserve or place the donor at increased risk of renal disease and prior treatment of malignant disease does not increase the operative risk of nephrectomy. A history of malignant disease may be acceptable if the specific cancer is curable and transmission of the cancer can reasonably be excluded; consultation with an oncologist may be required. Examples of cancers considered to have low risk for transmission include early prostatic and early low-grade bladder and cervical malignancies. Consent to receive a renal transplant must include a discussion with the donor and the recipient regarding the fact that risk of transmission of malignant disease cannot be completely excluded.

Cardiovascular and Pulmonary Disease

In prospective donors, the cardiac assessment should be based on the history, risk factors, examination, and electrocardiographic findings. An exercise or pharmacologic stress test and echocardiography may be warranted in certain circumstances. Individuals with myocardial dysfunction or coronary ischemia are at increased anesthetic risk and should generally not donate. Pulmonary contraindications to donation include chronic lung diseases that significantly increase the anesthetic risk. If indicated by history and examination, pulmonary function testing, echocardiography, or sleep studies should be performed. In all cases, donors should cease smoking for at least 8 to 12 weeks before surgery to minimize the risk of postoperative pneumonia.

COMPATIBILITY AND IMMUNOLOGIC CONSIDERATIONS

Blood Group Compatibility

Traditionally, transplantation across incompatible blood groups has been avoided because of the risk of hyperacute rejection mediated by preformed anti-A or anti-B antibodies to the carbohydrate blood group antigens, expressed by endothelial cells as well as by red blood cells. In recent years, ABO-incompatible transplantation has become more widespread, largely on the basis of excellent outcomes described initially by Japanese centers.[56] "Desensitizing" the recipient can avert hyperacute rejection. This involves removal of blood group antibodies by plasma exchange or immunoadsorption to achieve target titers. Preemptive splenectomy or rituximab administration (anti-CD20 monoclonal antibody) is often also used; however, the need for these measures is not clear.[57] Rejection is predicted by high initial antibody titers and high rebound titers early after transplantation.[58] A further period of plasma exchange or immunoadsorption after transplantation is commonly instituted, whereas other centers determine the need for these therapies preemptively based on post-transplantation antibody titers. With use of this protocol, patient and graft survival appears to be equivalent to that of blood group–compatible transplantation for the short to medium term (up to 9 years).[56] Longer-term results are awaited. A comprehensive overview and summary of current approaches relating to

antibody-incompatible transplants is available at the British Transplantation Society website, www.bts.org.uk.

Human Leukocyte Antigen Compatibility

"Tissue typing" of recipient and donor determines their HLA match. HLA antigens are coded on chromosome 6, with half (one haplotype) inherited from each parent. The major histocompatibility class I HLA-A and HLA-B and class II HLA-DR antigens are routinely determined, because rejection responses are thought to most commonly stem from mismatches at these alleles. There is an increasing awareness of the importance of immune responses to other HLA antigens, and many centers now look for the presence of antibodies to HLA-C, HLA-DQ, and HLA-DP. A six-antigen (HLA-A, HLA-B, and HLA-DR) match confers a graft survival advantage compared with 0 antigen matches for both cadaveric and living donor transplantation of 10% at 10 years.[59,60] In addition to determination of the HLA compatibility, crossmatching and screening for anti-HLA antibodies are performed to assess the risk of rejection.

Assessing Human Leukocyte Antigen Sensitization

The principle of screening for antibodies against HLA antigens using panel reactivity is shown in Figure 102-4. IgG antibodies against class I (HLA-A and HLA-B) antigens are highly associated with acute rejection and are a contraindication to transplantation. IgM antibodies against HLA antigens may also predict rejection if they are present in current but not past sera; however, they may also be falsely positive. Prior treatment of sera with dithiothreitol can remove IgM antibodies and aid in the interpretation of the test (Table 102-4). Autoantibodies (such as may occur in lupus) may also give false-positive results and can be determined by prior absorption with autologous lymphocytes.

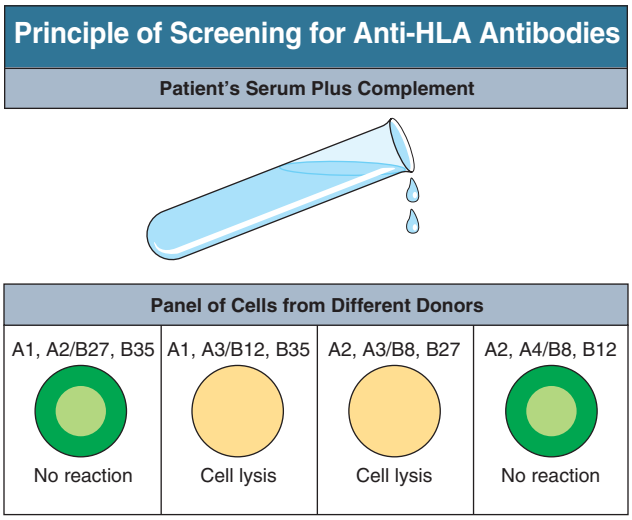

Figure 102-4 Principle of screening for anti–human leukocyte antigen (HLA) antibodies. The patient's serum is tested with a panel of cells of known HLA types. The most common HLA antigens are represented in such panels. In this example, the A3 antigen is the only antigen present in the two lysed cell populations and absent from the nonlysed samples. Therefore the patient's serum contains anti-HLA A3 antibodies.

Sensitization to HLA antigens generally occurs through blood transfusion, pregnancy, or prior transplantation. Presence in the recipient of antibodies to donor-specific HLA antigens can result in hyperacute rejection. Crossmatching of donor lymphocytes with recipient serum allows screening for this possibility. Terasaki and coworkers pioneered the complement-dependent cytotoxicity (CDC) crossmatch.[61] This assay determines the presence of antibodies thought to be of clinical significance by mixing donor T or B lymphocytes with recipient serum in the presence of complement. The sensitivity of the assay can be augmented by the addition of anti–human globulin. Presence of a positive T cell CDC crossmatch to the donor is highly predictive of hyperacute rejection,[61,62] whereas a B cell CDC crossmatch is more subject to false-positive results but should prompt a search for donor-specific antibodies.[63] A positive T cell crossmatch is an absolute contraindication to transplantation.

The flow crossmatch is more sensitive than the CDC in detecting antibody capable of binding to donor T or B lymphocytes. Binding of antibody from donor serum is detected by flow cytometry after probing with a fluorescein-labeled anti-immunoglobulin antibody. The predictive value of a positive flow crossmatch for rejection is less than that of a CDC crossmatch because of its increased sensitivity, and it does not assess the ability of the antibody to fix complement. In most centers, it is not routinely performed before deceased donor transplants, but it is commonly performed in a living donor transplant workup. A positive flow crossmatch (with a negative CDC crossmatch) is not an absolute contraindication to proceeding; however, it may lead to alteration of the immunosuppressive regimen (e.g., use of a desensitization protocol) to decrease the risk or severity of antibody-mediated rejection.

Determination of the presence of anti-HLA antibodies in the recipient's serum is increasingly used as a means of predicting rejection. This virtual crossmatch compares the specificity of the antibodies identified with the prospective donor's HLA typing. Donor-specific anti-HLA antibodies are correlated with worse graft survival even in the setting of a negative crossmatch.[64] Antibodies can be detected through panel reactive antibody testing, by enzyme-linked immunosorbent assay, or with more sensitive antigen-coated bead techniques. Beads are coated with a single HLA antigen and are mixed with recipient serum and probed with a fluorescein-labeled

Interpretation of the Crossmatch Test

Antibody to MHC Class	Crossmatch (Normal Procedure)		Crossmatch (Dithiothreitol)		Risk of Antibody-Mediated Graft Damage
	T Cells	B Cells	T Cells	B Cells	
IgG against class I	+	+	+	+	Yes
IgM against class I	+	+	–	–	Yes; IgM class I antibodies may be harmless if present in old sera only but not in the current serum
IgG against class II	–	+	–	+	Yes
IgM against class II	–	+	–	–	Unknown
IgM autoantibodies	+	+	–	–	No

Table 102-4 Interpretation of the crossmatch test. *MHC,* Major histocompatibility complex.

anti-immunoglobulin antibody. Beads that bind antibody are therefore identified by fluorescence. The decision on whether to proceed with transplantation in the context of this information is complex. Recommendations for detection and characterization of clinically relevant antibodies in solid organ transplantation are summarized by the British Society of Histocompatibility and British Transplantation Society and are available at www.bts.org.uk. A more recent set of guidelines was also published after a Consensus Conference on Antibodies in Transplantation, held in 2012.[66]

CHAPTER 103

Kidney Transplantation Surgery

Adam D. Barlow and Michael L. Nicholson

SOURCES OF KIDNEYS FOR TRANSPLANTATION

The usual and most frequent source of kidneys for transplantation has been donation after brain death (DBD), formerly known as donation from a heart-beating cadaveric donor. The increasing worldwide discrepancy between the availability of and the need for renal allografts[1] has led to the increasing use of alternative sources of organs, including donation after cardiac death (DCD) donors (previously known as non–heart-beating donors) and living donors. The evaluation and selection of donors are discussed in Chapter 102. Here we discuss surgical aspects of retrieval and transplantation of kidneys.

DONATION BEFORE CARDIAC DEATH DONORS

The potential DBD donor is maintained by artificial ventilation in a critical care setting until death has been diagnosed by brainstem death criteria,[2] the consent of the next of kin for donation has been given, and the necessary legal and institutional approvals have been obtained.

In the operating room the initial step is cannulation of the aorta and inferior vena cava while the heart is still beating. This allows perfusion of the organs with cold preservative solution immediately before cardiac arrest, minimizing warm ischemia. The priorities of the organ retrieval team are influenced by the range of organs being donated. Heart, lung, and liver retrieval take priority over kidney retrieval, which may significantly lengthen the ischemic time. The kidneys are removed *en bloc,* and typically the artery is retrieved with a cuff of aorta (Carrel patch), with the maximum achievable length of renal vein, and 10 to 15 cm of ureter. The length of the right renal vein may be maximized by including a portion of inferior vena cava in continuity. Care is taken to avoid damage to polar and other accessory arteries, especially the lower pole artery, which may supply the ureter; stripping of adventitial tissue from the ureter must also be avoided, because this may also compromise its blood supply.

The kidneys are flushed with ice cold preservation fluid until the effluent is clear and then are stored for transport in crushed ice or on a perfusion machine (see the discussion of renal preservation).

DONATION AFTER CARDIAC DEATH DONORS

Before consensus was reached regarding the definition of brainstem death, DCD donors were the main source of transplant organs. These donors were intensive care unit based and had suffered head injuries or cerebrovascular accidents deemed irrecoverable, but organ retrieval could proceed only after cardiorespiratory death. This changed with the introduction of brainstem death legislation, but the use of DCD kidneys has recently increased again in response to the shortage of suitable organs for transplantation. An international consensus has defined categories of DCD donors[3] to facilitate legal and ethical discussion and to highlight possible differences in organ viability (see Box 102-3). DCD kidneys sustain a period of warm ischemia, the period between cardiac arrest and the time that *in situ* cold perfusion is started. The duration of ischemia correlates with rates of primary nonfunction, delayed graft function, acute rejection, allograft, and patient survival. The main requirement of organ procurement from DCD donors is therefore to achieve rapid *in situ* perfusion of the kidneys to limit warm ischemia. This requires an emergency response team of surgeons and transplant coordinators, with considerable on-call and logistic commitments.

Donation after cardiac death donors may be either uncontrolled (Maastricht categories I and II) or controlled (Maastricht categories III through V). In controlled donors, cardiac arrest is expected, and it is therefore possible to reduce the warm ischemia time to only a few minutes because the surgical retrieval team will be on standby. Unexpected donor cardiac arrest may result in prolonged warm ischemia times. The duration of reversible warm ischemia time that the human kidney can sustain is unknown, but DCD kidneys with warm ischemia exceeding 60 minutes are considered by many to be of marginal suitability.

Donation After Cardiac Death Protocol

Centers involved with DCD donation should adhere to the Maastricht protocol,[4] which includes the following principles:

- Approval by the local medical ethics committee
- Diagnosis of death by doctors who are independent of the transplantation team
- 10-minute rule (after declaration of cardiac death, the body is left untouched for a period of 10 minutes before intervention)
- Rapid *in situ* cooling with use of a catheter inserted into the aorta
- Organ retrieval by standard surgical techniques

Uncontrolled DCD Donors

After a period of unsuccessful resuscitation, confirmation of cardiac death, and observation of the 10-minute rule, cardiac massage and ventilation with 100% oxygen are recommenced in an attempt to deliver oxygenated blood to the kidneys. A mechanical resuscitation device may be used. *In situ* renal cooling is effected by placing a double-balloon, triple-lumen perfusion catheter into the aorta via a femoral artery cut-down (Fig. 103-1), with instillation of preservation solution. Alternatively, the donor can be moved to an operating room as soon as death has occurred, and the aortic perfusion catheter is placed directly at laparotomy rather than via a femoral artery cut-down.

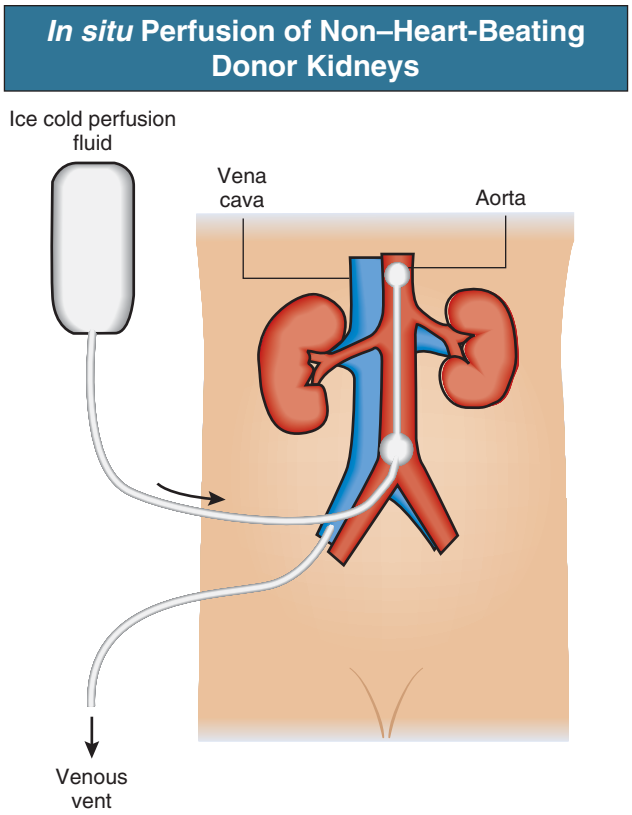

Figure 103-1 Technique for *in situ* perfusion of donation after cardiac death kidneys. A double-lumen, double-balloon arterial catheter is introduced through the femoral artery and the lower balloon inflated at the aortic bifurcation and the upper balloon above the renal arteries. Ice-cold perfusion fluid is introduced and vented through the femoral vein until the effluent becomes clear.

Controlled DCD Donors

For controlled DCD donors, the transplantation team awaits cardiac arrest; after confirmation of death, the 10-minute rule is observed, and then the perfusion catheter is inserted via the femoral artery. Alternatively, the patient can be taken to the operating room before cardiac death if the next of kin gives consent.

LIVING KIDNEY DONORS

In the United States in 2011, 32% of renal transplants were from living donors,[5] compared with 40% in the United Kingdom.[6] After a rapid increase in living donor transplantation at the beginning of this decade, rates have become more static. Superior recipient post-transplantation outcome compared with use of kidneys from deceased donors,[7] the potential for preemptive transplantation before dialysis, and the ability to plan the procedure (allowing optimization of recipient condition) are major advantages and justify continued efforts to expand use of living donors. The medical evaluation of the living donor is discussed in Chapter 102 (see Boxes 102-5 and 102-6).

Preoperative Imaging

Preoperative imaging of living donors confirms the presence of two functioning kidneys, indicates pathology that would preclude donation, and provides anatomic information necessary for planning the procedure. Imaging assumes paramount importance before minimal access donor nephrectomy because of the reduced operative exposure and particular difficulties in the identification of complex renal vein tributaries. The location, size, and number of renal veins and tributaries needs to be accurately described preoperatively. Angiography combined with excretion urography is now obsolete. For preoperative description of the main renal artery and vein anatomy, magnetic resonance angiography and computed tomographic angiography are comparable,[8] but computed tomographic angiography is more sensitive and specific for complex vascular anatomy and provides excellent correlation between imaging and surgical findings[9] (Fig. 103-2).

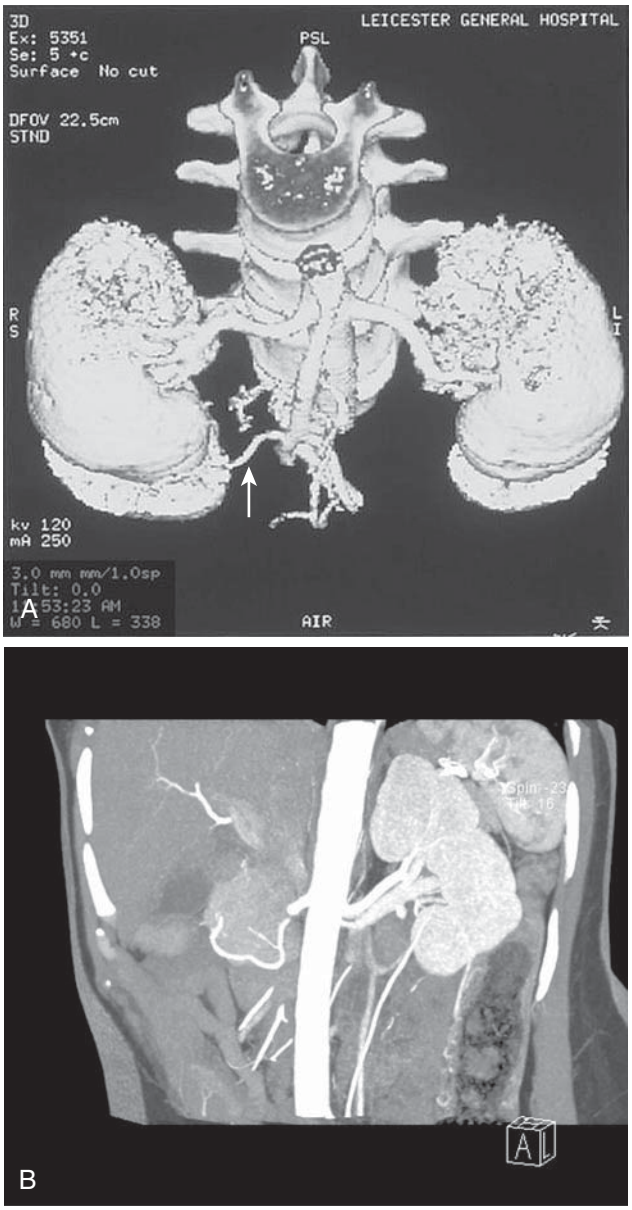

Figure 103-2 Living donor preoperative computed tomographic angiogram. A, Three-dimensional reconstruction of arterial supply. Note the lower pole artery to the right kidney *(arrow),* which may supply the ureter as well as the lower pole parenchyma. **B,** Conventional image showing single artery and vein to the left kidney.

Minimal Access (Laparoscopic) Donor Nephrectomy

Living donor nephrectomy has traditionally been performed through an open incision, necessitating a prolonged period of recovery. This

Figure 103-3 Flank wound from open nephrectomy.

Donor Benefits of Minimally Invasive Donor Nephrectomy
• Shorter incisions • Less pain • Shorter hospital stay • Shorter recovery • Better cosmetic appearance

Box 103-1 Donor benefits of minimally invasive donor nephrectomy.

and the cosmetic implications of a large flank wound may discourage potential donors (Fig. 103-3). To reduce such disincentives, there has been a move toward minimally invasive donor nephrectomy, first performed as a transperitoneal laparoscopic procedure (laparoscopic donor nephrectomy [LapDN]).[10] LapDN is associated with decreased severity and duration of postoperative pain, shorter in-patient stay, quicker return to work and normal activities, and improved cosmetic result when compared with open donor nephrectomy[11] (Box 103-1). Furthermore, the overall societal cost of LapDN is lower,[12] and recipient quality-of-life scores are higher.[13] The procedure is, however, technically demanding, and there is potential for damage to the renal parenchyma, vessels, and ureter during dissection. It takes longer than open nephrectomy and exposes the allograft to a longer period of warm ischemia.[11]

Nevertheless, retrospective data suggest that minimal access donor nephrectomy not only offers postoperative advantages to the donor, but also increases the number of transplants performed by reducing donor disincentives; estimates range from a 25% to a 100%[14] increase in transplantation activity. The widespread introduction of LapDN at the beginning of this decade saw an initial dramatic increase in the number of live kidney donors. However, rates have been static in both the United States and the United Kingdom over the last 5 years, suggesting that we may have seen the maximum benefits of this effect. Three minimal access approaches have been described: transperitoneal, extraperitoneal, and hand-assisted living donor nephrectomy.

Transperitoneal Laparoscopic Donor Nephrectomy

Pneumoperitoneum is established and four laparoscopic ports are usually required (Fig. 103-4). After laparoscopic dissection a

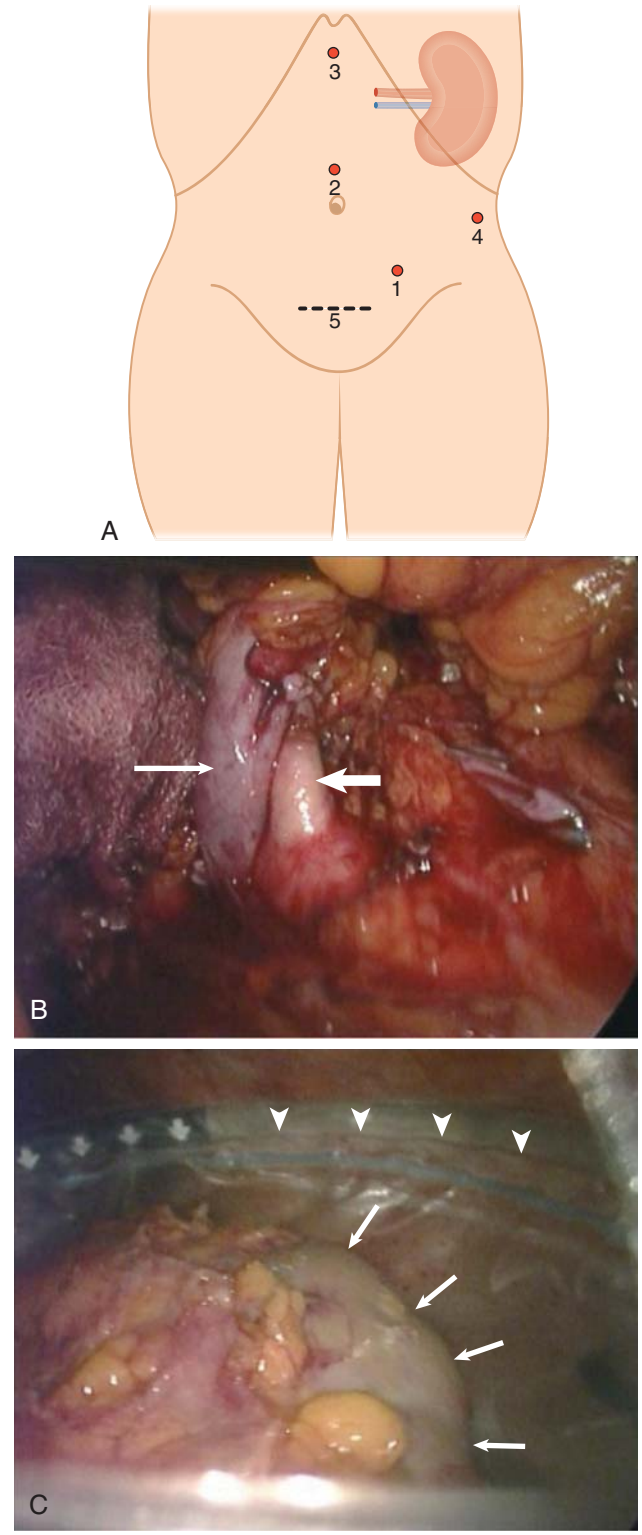

Figure 103-4 Technique for laparoscopic donor nephrectomy. **A,** Positions for four laparoscopic ports (*1* to *4*) and Pfannenstiel incision *(5)* through which the kidney is removed. **B,** Intraoperative view showing left renal artery *(short arrow)* and vein *(long arrow)* prepared for control and division. **C,** Intraoperative view showing the kidney (*arrows* mark lateral margin) placed in the endoscopic retrieval bag *(arrowheads mark the edge of the bag).*

Pfannenstiel incision is made through which the kidney is brought out within an endoscopy retrieval bag after control and division of the artery vein and ureter.

Hand-Assisted Laparoscopic Donor Nephrectomy

The hand-assisted technique allows tactile sense to facilitate dissection, retraction, and exposure. It is said to be easier to learn and can be safely and efficiently performed by surgeons with less laparoscopic experience. The hand-assist device allows the operator's nondominant hand to enter the abdomen through an airtight system.

Retroperitoneoscopic Operative Technique

The retroperitoneal approach avoids breaching the peritoneum, displays the renal anatomy in a very different manner, and may be easier for retrieving the full length of the vessels, especially on the right side. The disadvantage is that a more limited operating space is available than with the transperitoneal or hand-assisted laparoscopic techniques.

Contraindications to Minimal Access Donor Nephrectomy

There are no absolute contraindications other than those applying to the open operation. The relative contraindications are dictated by donor factors and the experience of the surgeon. The donor must be fit for anesthesia, including the physiologic stress of pneumoperitoneum. Obesity is a relative contraindication for both open and laparoscopic surgery, and the hand-assisted approach may be better suited in such patients. Previous abdominal surgery is a further relative contraindication because of the potential for adhesions. Multiplicity of renal vessels should not hinder LapDN.

Effect of Pneumoperitoneum

Transient intraoperative oliguria secondary to decreased renal blood flow is a frequent occurrence during laparoscopic procedures. Proposed mechanisms include decreased cardiac output, renal vein compression, ureteral obstruction, renal parenchymal compression, and systemic hormonal effects. Intracranial pressure increases during pneumoperitoneum, with release of vasoconstrictor agents that decrease renal blood flow. Use of a lower pressure reduces the adverse effects of pneumoperitoneum on renal perfusion. In donor nephrectomy, impaired renal blood flow may compromise early allograft function and compound the damaging effects of warm and cold ischemia and operative manipulation of the kidney. Laparoscopically derived donor kidneys have higher serum creatinine up to 1 month post-transplantation compared with open surgery, but thereafter graft function is equivalent.[15] The pioneers of LapDN used high volumes of crystalloid preoperatively and intraoperatively to maintain renal perfusion in the presence of pneumoperitoneum. The authors have seen two episodes of unilateral pulmonary edema in the dependent lung, and we now recommend volume loading the donor with 2 liters of crystalloid the night before surgery and only using replacement fluid during surgery. This protocol has led to no apparent detriment to graft function.

Graft Function and Acute Rejection

There is no consistent evidence that graft function differs among kidneys retrieved by open, laparoscopic, or hand-assisted donor nephrectomy. The exception is that rates of delayed graft function and acute rejection may be higher in pediatric recipients, especially the 0- to 5-year age group.

Pretransplantation ischemia could, in theory, render the donor kidney more immunogenic by inducing major histocompatibility complex (MHC) class II expression. However, despite the longer warm ischemia time, acute rejection rates and severity of rejection are not higher in laparoscopic than in openly retrieved living donor kidneys.

Technical Issues

Ureteral ischemia was more common in early experience of LapDN but can be avoided if care is taken to ensure that sufficient periureteral tissue is taken and that the dissection does not occur too close to the renal pelvis.

Multiple arteries need not be a barrier to successful use of grafts from laparoscopic donors. In open donor nephrectomy, the right kidney is retrieved in 20% to 30% of procedures, whereas LapDN uses the right kidney in less than 10%,[16] reflecting concern over the operative safety of the right-sided laparoscopic operation, principally the difficulties involved in obtaining an adequate length of renal vein. It has been argued that this practice has led to compromise of the principle that the better kidney should remain with the donor.

Postoperative Recovery

After uneventful open nephrectomy, the donor can expect to be discharged from the hospital in 5 to 6 days and is able to return to work after 3 to 6 weeks, although return to work has been shown to be 2 to 3 weeks later in open nephrectomy compared with LapDN.[11] After LapDN the donor usually leaves hospital in 2 to 4 days and can return to work in 3 to 6 weeks.

Choice of Donor Operative Technique

The choice of operative procedure depends on the local expertise of the surgeons. There is accumulating evidence that the laparoscopic operation removes some of the disincentives to donation, and this approach is likely to be adopted widely in the future.

RENAL PRESERVATION

Preservation of deceased donor organs is crucial to allow time for matching, sharing of organs, and preparation of the recipient. Damage from hypothermia and reperfusion must be minimized. There is little standardization of the type of preservation solution used. Marshall's hyperosmolar citrate solution and histidine-tryptophan-ketoglutarate are popular choices in Europe, but University of Wisconsin (UW) solution is more commonly used in the United States because extended preservation times are more often required.

Organs can be preserved by cold storage (kept in crushed ice after flushing with preservation solution) or by machine-driven pulsatile perfusion. The proposed benefits of machine perfusion come from allowing aerobic function through provision of oxygen and substrate and removal of metabolic end products. Although machine perfusion has been used for many years, there is still no consensus about its superiority to cold storage nor about the best perfusion parameters. Recent randomized trials have yielded conflicting results; a U.K. trial of DCD kidneys showed no benefit,[17] whereas a European trial demonstrated reduced delayed graft function in deceased donor transplants after machine perfusion.[18]

A novel approach to kidney preservation, only recently introduced into clinical practice, is *ex vivo* normothermic perfusion. Early results are promising,[19] but the technique needs to be studied in larger clinical trials.

Decisions on the use of a kidney from a marginal donor can be supported by data from machine or normothermic perfusion; high

perfusion pressures are associated with primary nonfunction and delayed graft function.

RENAL TRANSPLANTATION PROCEDURE

The transplanted kidney is placed heterotopically in one or other iliac fossa. The inferior epigastric vessels are ligated, as is the round ligament of the uterus in female patients. Occasionally the inferior epigastric artery may be preserved and used for revascularization of small polar arteries. In male patients the spermatic cord is mobilized and preserved. The peritoneum should not be breached, but instead swept superiorly to reveal the extraperitoneal bed into which the transplanted kidney will be placed. The iliac blood vessels are then mobilized, with care taken to meticulously ligate all the associated lymphatic channels to reduce the risk of post-transplantation lymphatic leak.

Vascular Anastomosis

The renal vein is anastomosed end to side to the external iliac vein. The arterial anastomosis can be performed either end to side to the external iliac artery or end to end to the divided internal iliac artery (Fig. 103-5). The end-to-side anastomosis is technically easier and is the usual method used in cadaveric transplantation, where it is possible to include a Carrel aortic patch with the renal artery.

With living donor kidneys it is not possible to include a Carrel patch, and occasionally a cadaveric kidney may be provided without a useable patch. In these circumstances the options are to anastomose the renal artery end to end to the divided internal iliac artery or end to side to the external iliac artery. Use of an aortic punch to create a circular arteriotomy may facilitate the latter technique. For living donor kidneys most surgeons use the external iliac artery. It is the authors' experience that positioning the kidney is often easier if the internal iliac artery has been used for the anastomosis, but this does risk buttock claudication and increases the risk of erectile dysfunction.

After completion of the vascular anastomoses, the kidney must sit in such a position that the renal vessels are not kinked. The transplanted kidney can be placed laterally in the iliac fossa or may be placed in a subrectus pouch fashioned specifically for the purpose.[20] In the latter case the renal vessels run laterally from the kidney, and this needs to be noted when a post-transplantation biopsy is performed. An operative diagram of the position of the kidney and vessels is therefore an important component of the clinical notes.

If there are multiple renal vessels, the number of anastomoses should be minimized. This can usually be achieved by careful bench surgery before implantation. If there are two or more renal arteries, their aortic patches are joined in such a way that a single arterial anastomosis is required. If necessary, recipient iliac artery or saphenous vein is used to facilitate reconstruction. Occasionally, small polar arteries will be recognized only after a kidney has been retrieved, and it is particularly important to reanastomose lower polar arteries accurately because these may provide all the ureteral blood supply. In the case of double renal veins, the most common course of action is simply to ligate the smaller vein; the larger one is usually sufficient to drain the whole kidney. If there are two equally sized veins, both may need to be anastomosed separately to the external iliac vein.

Urinary Drainage

The traditional method of ureteral anastomosis is the Politano-Leadbetter technique, involving a transvesical ureteroneocystostomy

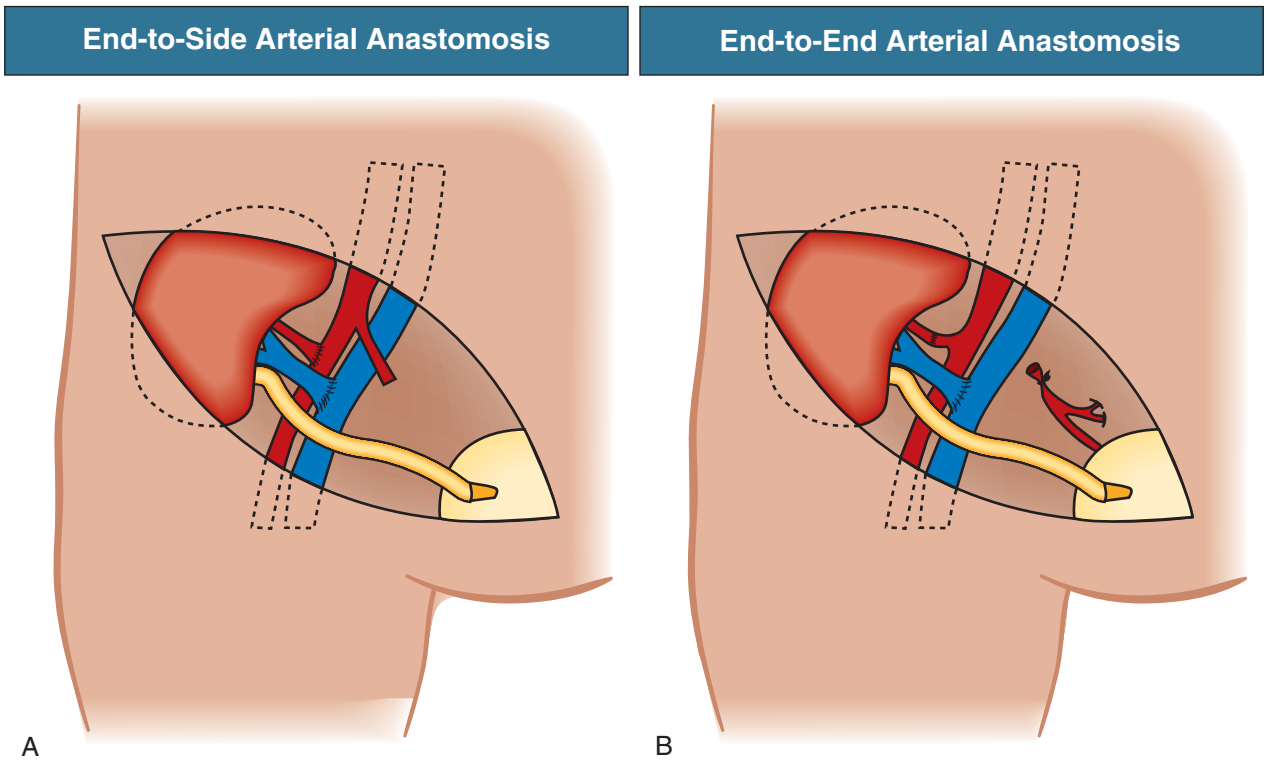

Figure 103-5 Vascular anastomosis techniques for renal transplantation. A, End-to-side anastomosis to the external iliac artery. **B,** End-to-end anastomosis to the divided internal iliac artery, suitable for living donor transplantation in which no aortic patch is available.

with creation of a submucosal antireflux tunnel. The end of the transplanted ureter is drawn through a submucosal tunnel from outside to inside and sutured to the bladder mucosa. The majority of surgeons now prefer the technically simpler extravesical ureteroneocystostomy onlay in which the spatulated end of the ureter is anastomosed to the cystostomy and the divided muscle layer is then resutured over the ureter to create a short antireflux muscle tunnel. The onlay method has the advantage of being possible with only a short length of ureter. The shorter the ureter, the less likely it is that there will be an inadequate blood supply to the distal end, thereby reducing the risks of ischemic ureteral leaks or stenosis. A temporary double-J ureteral stent is usually placed. Stents reduce the impact of small technical errors while the ureter is leaking, and reduce major urologic complications to an incidence of 1.5%.[21] However, they are a potential source of urinary infection, can become encrusted or blocked by debris, and can migrate or fragment. Nevertheless, antibiotic prophylaxis is not justified because it increases the risk of infection with multiresistant organisms. A further danger is the forgotten stent that has not been removed, which should always be considered in patients with unexplained and persistent lower urinary tract symptoms after transplantation. Stents are usually removed 4 to 6 weeks post-transplantation, and this can be performed without general anesthesia with use of a flexible cystoscope.

Alternative Techniques of Urinary Reconstruction

Renal transplantation is quite commonly performed in patients who have abnormal bladders. In many patients it is possible to anastomose the transplanted ureter to the bladder in the hope that the bladder can be rehabilitated, if necessary, with use of post-transplantation intermittent self-catheterization. Nonetheless, some patients require urinary diversion with an ileal conduit. The conduit should be fashioned at least 6 weeks before transplantation, but it may have been present for many years. If so, a contrast study (a conduitogram) should be performed before transplantation to exclude the development of conduit stenosis, although this is rare. The transplanted kidney is best placed in the ipsilateral iliac fossa to avoid tension in the ureter, and it may be preferable to deliberately place the transplanted kidney upside down so that the ureter runs cranially and has a more direct route to the conduit. After revascularization, the peritoneum is opened and the ureter is anastomosed to the conduit over a double-J stent. Excellent long-term results have been achieved with this technique.[22]

Drainage and Wound Closure

Both the transplant bed and the subcutaneous tissues may be drained to prevent the accumulation of serosanguineous fluid or lymph around the transplanted kidney, although many surgeons no longer routinely place drains. The skin is best closed with a subcuticular absorbable suture and then dressed with a clear adhesive dressing so that ultrasound scanning can be performed early without disturbing the wound. For this reason, metal clips are never used for the skin.

Postoperative Course

The recipient is nursed in a general ward with standard precautions and no need for reverse barrier nursing. There is no benefit to continuing prophylactic antibiotics beyond a single dose given at induction of anesthesia. Prophylaxis against thromboembolic disease is in the form of thromboembolic deterrent (TED) stockings and low-molecular-weight heparin is continued until discharge. Oral fluids and diet are commenced as tolerated immediately after surgery. Maintenance immunosuppressive agents are given orally, except in the presence of a prolonged postoperative ileus with high volumes of nasogastric drainage, when they should be administered intravenously. If recovery is straightforward, the bladder catheter and wound drains are usually removed by day 5, and the recipient is fit for discharge after 7 to 10 days to be kept under close outpatient monitoring.

SURGICAL COMPLICATIONS OF RENAL TRANSPLANTATION

There is a small but significant incidence of technical complications, which can be minimized by avoiding damage to the kidneys at the time of the retrieval. Nonetheless, the presence of multiple renal vessels and donor atherosclerotic disease does increase the likelihood of technical problems in the recipient, as do recipient obesity, atherosclerosis, and previous transplantation. Algorithms to aid in the management of complications in the early post-transplant period can be found in Figures 103-6 and 103-7.

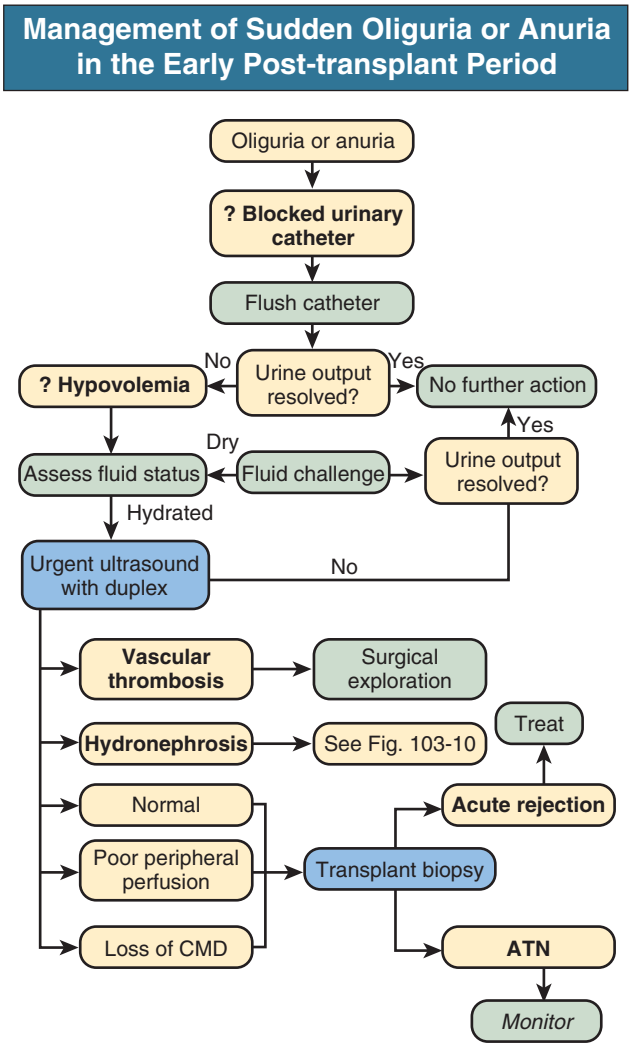

Figure 103-6 Management of sudden oliguria or anuria in the early post-transplant period. *ATN,* Acute tubular necrosis; *CMD,* corticomedullary differentiation.

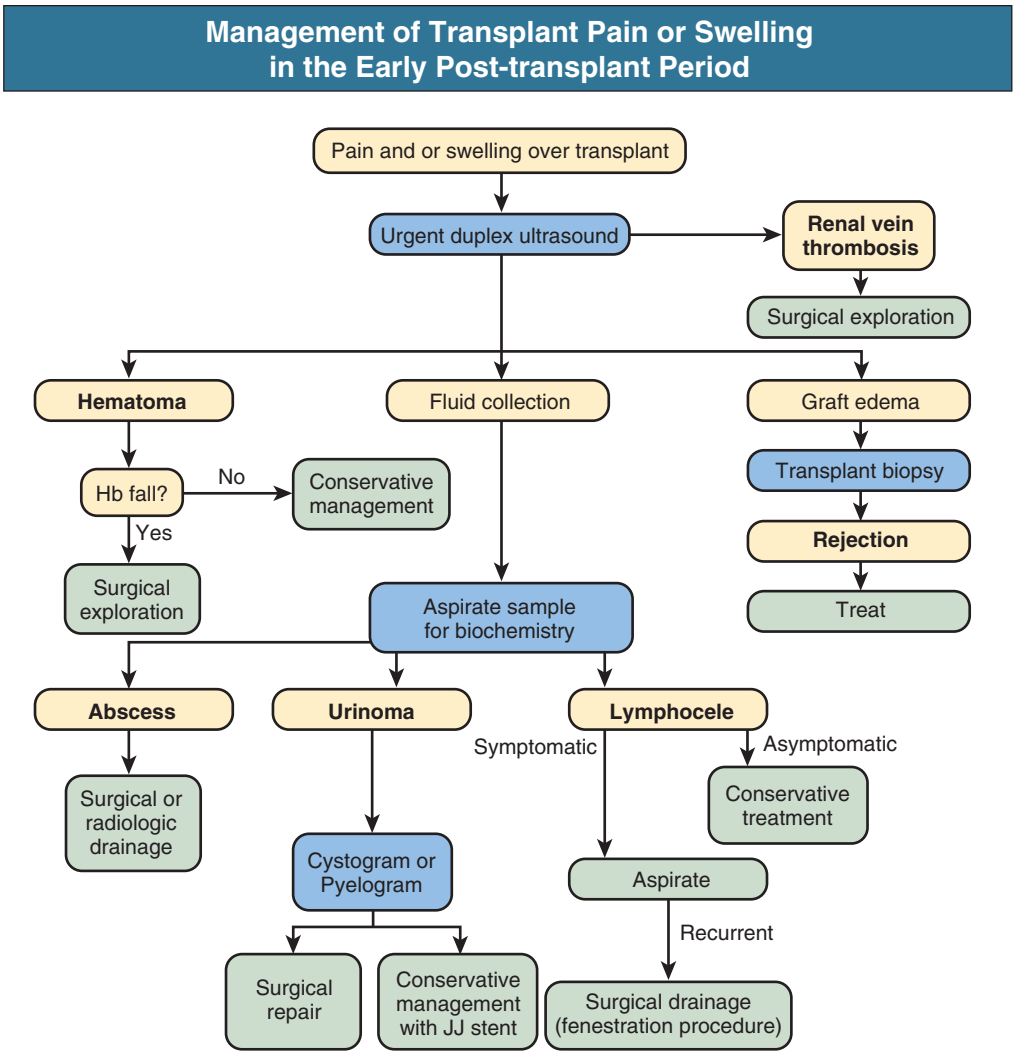

Figure 103-7 Management of transplant pain or swelling in the early post-transplant period. *Hb,* Hemoglobin.

Wound Infection

The use of preoperative prophylactic antibiotics, commonly amoxacillin-clavulanic acid, has reduced the incidence of wound infection to less than 1%. If a wound infection does occur, treatment is with antibiotics, guided by microbiologic wound swabs, and drainage of collections as necessary.

Wound Dehiscence

The risk of wound dehiscence is increased in obese and diabetic patients and those receiving sirolimus. Identification and treatment of any infection are mandatory. Resuturing of the wound is rarely justified. Large areas of dehiscence often benefit from vacuum-assisted closure, but the majority require only frequent dressing.

Vascular Complications

Transplant vascular thrombosis is a feared complication that may cause early and irreversible graft failure. Although there are also significant hemorrhagic risks, routine perioperative prophylaxis should be given with subcutaneous low-molecular-weight heparin, and some units prescribe aspirin for the first few postoperative months.

Bleeding from Vessels in the Renal Hilum

Careful postoperative observation and regular hemoglobin and hematocrit measurements are crucial for the early detection of bleeding. Output from the transplant drains may give an early indication of heavy blood loss. Unsecured small vessels in the renal hilum may not be obvious during surgery, but they may start bleeding postoperatively. This form of blood loss can be slow, persistent, and serious. If the patient's condition allows, urgent imaging may be performed to secure a diagnosis, but the best course of action is usually emergency exploration of the transplant under general anesthesia.

Anastomotic Hemorrhage

Anastomotic hemorrhage is a rare occurrence, usually caused by a technical surgical error, and is more common with multiple arteries and the use of antiplatelet agents.[23,24] Early after transplantation, the patient may report pain over the graft. This symptom should always be taken seriously. There may also be pain in the back or the rectum caused by a tension hematoma in the retroperitoneum or pelvis. Significant hemorrhage will be attended by circulatory collapse, with tachycardia and hypotension. There will be a decrease in the hemoglobin and hematocrit, sometimes to alarmingly low levels. The patient must be returned to the operating room immediately and the transplant reexplored.

Hemorrhage can also occur some weeks after transplantation because of the development of a mycotic aneurysm of the renal artery. In the rare case of a ruptured mycotic aneurysm, an immediate graft nephrectomy is required, but the mortality is high.

Renal Artery Thrombosis

Renal artery thrombosis is a rare event, occurring in less than 1% of transplants. The usual outcome is loss of the kidney. Acute arterial thrombosis may occur intraoperatively or during the first days or weeks post-transplantation. Potential causes include hyperacute rejection or a procoagulant state, but most cases are caused by a technical error during the anastomosis of small or atheromatous vessels.[24] Successful vascular anastomosis requires that the vessels are not under tension and that there is a smooth transition between the two endothelial surfaces; sutures must be placed through all layers of the vessel walls so that an intimal flap is avoided. Vascular adventitia is thrombogenic and must be excluded from the lumen of the anastomosis. The risk of renal artery thrombosis is increased in the presence of atherosclerosis, persistent hypotension, volume depletion (e.g., diarrhea, excessive preoperative dialysis), and prothrombotic states, including diabetes.

Renal arterial thrombosis presents with sudden anuria, the differential diagnoses being a blocked urinary catheter, dehydration, acute tubular necrosis, or a urologic complication. A high index of suspicion is required to make this diagnosis, particularly in the immediate postoperative period. The only worthwhile investigation is an urgent duplex ultrasound scan, but if the diagnosis is seriously entertained, then the only hope of saving the transplant is to reexplore it immediately in the hope that a correctable cause can be found. The reality is that unless the acute arterial thrombosis occurs during surgery, there is little chance of saving the transplanted kidney. Acutely thrombosed grafts must nevertheless be explored and removed to avoid the development of sepsis in a necrotic graft, a potentially fatal complication.

Renal Vein Thrombosis

Renal vein thrombosis is more common than arterial thrombosis and occurs in 1% to 6% of renal transplants.[24,25] Although it may result from a technical error at the time of surgery, its cause is usually less certain. The renal vein can certainly be twisted or kinked if it is not correctly placed after completion of the vascular and ureteral anastomoses. The peak incidence of renal vein thrombosis is 3 to 9 days post-transplantation[26]; a transplant patients with good initial graft function will have a sudden loss of urine output, which is often markedly blood stained, associated with severe pain arising from swelling and (very rarely) rupture of the allograft. The ipsilateral leg may also swell if there is involvement of the iliac venous system. Renal vein thrombosis may also be occult and is one differential diagnosis of delayed graft function. Duplex ultrasound scanning is the best investigation. In an established renal vein thrombosis this may show an obviously swollen allograft with surrounding hematoma and an absence of renal perfusion. Lesser degrees of thrombosis, or indeed incipient thrombosis, may be highlighted by an absence of arterial flow in diastole. An even later development is a reversal of flow in diastole.

As with arterial thrombosis, if this diagnosis is entertained, then the best course of action is to reexplore the transplant as an emergency. The renal vein anastomosis can be opened to allow clot to be extracted, and the venotomy is then closed and the kidney observed for improvement. A more radical alternative is to immediately explant the kidney by taking down the arterial, venous, and ureteral anastomoses. The kidney can then be reflushed with cold perfusion fluid on the back table and held in preservation fluid at 4° C. This allows much more time to assess the cause of the venous thrombosis, and if the kidney remains viable, the transplant operation can then be repeated. If the transplant is already infarcted or cannot be adequately flushed with preservation fluid, then the organ will need to be discarded anyway and nothing is lost by immediate explantation. Successful emergency surgical exploration with subsequent long-term function is rare. Interventional radiographic techniques offer an alternative to surgery. The renal vein can be selectively catheterized via the ipsilateral femoral vein, and graft thrombolysis may then be attempted. This technique is particularly useful when renal vein thrombosis occurs late after transplant and the risk of systemic anticoagulation is low. The use of various thrombolytic agents has been reported, including heparin, urokinase, streptokinase, and tissue plasminogen activator (tPA), with no consensus as to which is the most appropriate.

Transplant Renal Artery Stenosis

Transplant renal artery stenosis is a later complication occurring 3 to 48 months after transplantation. Not all stenoses are of functional or clinical significance, as shown by studies in which all functioning transplants have undergone angiography.[27] Causal factors include donor and recipient atherosclerosis, factors associated with surgical technique, and severe acute rejection.[28] The presentation and management of transplant renal artery stenosis are discussed in Chapter 66.

Lymphocele

Small, clinically insignificant lymphatic collections can be demonstrated by ultrasound scan in up to 50% of renal transplants.[29] Larger lymphoceles that cause complications or require treatment occur in 2% to 10% of patients.[30] The source of peritransplant lymph leaks is the lymphatic channels around the iliac arterial system rather than the lymphatics of the transplanted kidney itself.[31] Therefore, during the dissection of the iliac arterial system, all the surrounding lymphatic channels must be meticulously secured with nonabsorbable ligatures or metals clips. Wound suction drains should not be removed postoperatively until less than 30 ml of fluid is produced on 2 consecutive days. It is safe to leave drains in place for several weeks post-transplantation to allow a low-volume lymphatic leak to seal by gradual fibrosis. Despite the theoretical risk of infection, this does not seem to be a problem in practice. If necessary, the patient can be discharged from the hospital with the drain *in situ.*

Compression of the transplanted ureter leading to renal dysfunction is produced only by very large lymphoceles (volume >300 ml). The peak incidence is at 6 weeks, but a lymphatic collection may present 2 weeks to 6 months after transplantation.[29] Most lymphatic collections are found anterior to the iliac vessels and lying between the transplant and the bladder (Fig. 103-8). Presenting features may include wound or ipsilateral thigh swelling in association with suprapubic discomfort and urinary frequency caused by bladder compression. Other presentations include pain over the transplanted kidney sometimes associated with fever, ureteral obstruction with graft dysfunction, and ipsilateral thrombophlebitis. However, the vast majority are asymptomatic and present as an incidental finding during an ultrasound scan being performed for another reason. It is important to aspirate all peritransplant fluid collections under ultrasound control to aid diagnosis. Macroscopic findings are usually sufficient to differentiate infected from noninfected lymph, and biochemical analysis of the fluid allows a urine leak to be excluded. Computed tomography or magnetic resonance imaging is an essential investigation if surgery is being contemplated, particularly if a laparoscopic procedure is planned. This allows accurate definition of

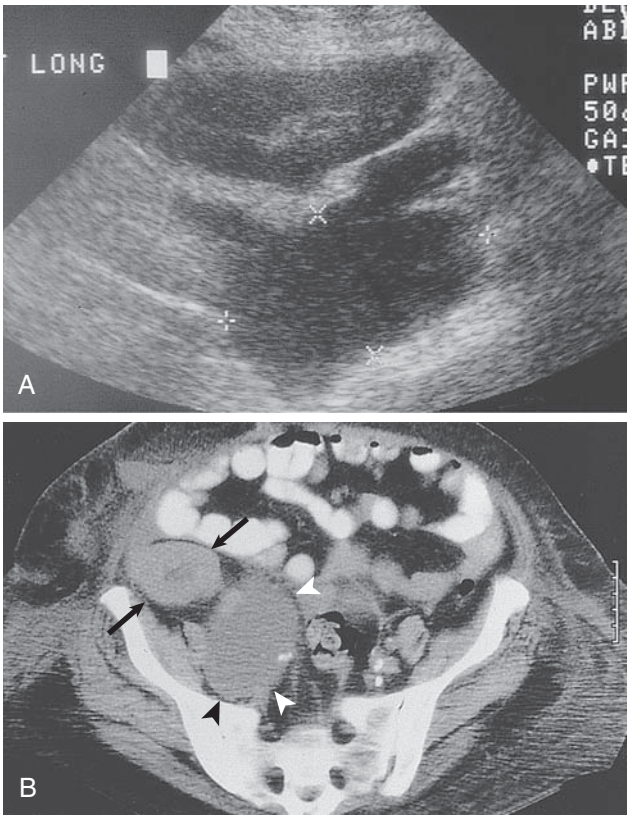

Figure 103-8 Post-transplantation lymphocele. A, Ultrasound appearance. A large echolucent lymphocele can be seen inferior to the transplanted (marked by *crosses*). **B,** Computed tomography appearance. A 5- × 5-cm lymphocele *(arrowheads)* is present under the transplanted kidney *(arrows)*.

the relationship between the lymphocele and the transplanted ureter. If the ureter is bow-strung across the superior surface of the lymphocele, then it could be damaged during a laparoscopic fenestration procedure.

Many small lymphoceles are asymptomatic and will resolve spontaneously given enough time. If action is deemed necessary, first-line treatment is aspiration under ultrasound control. If there is a recurrence, further aspirations can be performed or an external drain can be placed with ultrasound guidance. If these simple measures fail, then open or laparoscopic surgical drainage may be required. A 5-cm diameter disk of the lymphocele wall is removed to create a large opening into the peritoneal cavity, allowing reabsorption of the lymph through the abdominal lymphatic drainage system. These peritoneal fenestrations have a tendency to heal before the lymphocele is completely reabsorbed, leading to early recurrence; a metal or omental plug may prevent this.

Urologic Complications

Urinary tract complications are relatively common after renal transplantation, with an incidence of 5% to 14%.[32] Although they can be difficult to manage, they only rarely cause graft loss or mortality. The relatively high incidence of urologic problems is a consequence of the tenuous blood supply of the transplanted ureter. After kidney retrieval, the only ureteral blood supply that is preserved is derived from the renal artery near the hilum of the kidney, and this can be easily damaged during retrieval.

Urinary Leaks

Urinary leaks most commonly occur because of ischemic necrosis in any part of the transplanted urinary collecting system. The distal ureter has the poorest blood supply and is therefore the most common site. Less commonly, leaks occur from the renal pelvis or the midportion of the ureter, which may be a result of unrecognized direct damage to the ureter during organ retrieval. Urinary leaks tend to occur in the first few days after transplantation but can present much later. The usual presentation is with straw-colored fluid leaking directly from the transplant wound or accumulating in the drains in association with oliguria. Alternatively, extravasating urine may accumulate as a peritransplant fluid collection. This presents as a painful swelling of the wound, and the patient may have a fever. In either case, the extravasated fluid must be differentiated from lymph by biochemical analysis of the fluid and a simultaneous serum sample. Urine will have markedly elevated urea and creatinine levels compared with the patient's serum, whereas lymph will have a similar biochemical profile.

The presence of a urinary fistula should be confirmed by antegrade or retrograde pyelography. Both of these techniques present challenges. Antegrade puncture of a nondilated pelvicaliceal system is technically difficult but usually possible. Retrograde cannulation of the transplanted ureteral orifice can be attempted with a flexible cystoscope. This is also a difficult maneuver because the transplanted ureter is implanted into the dome of the bladder rather than at its base. If the urine leak is contained as a urinoma, ultrasound will demonstrate a fluid collection between the transplanted kidney and the bladder, which can be sampled by needling or drained by the placement of a suitable percutaneous catheter.

The management of urinary leaks has changed significantly in recent years. The former practice of early reexploration and surgical reconstruction[33] is no longer always necessary. Interventional radiographic techniques offer an alternative, at least for initial treatment. The aim is to place a double-J (pigtail) ureteral stent across the region of damage via an antegrade nephrostomy; this may allow time for the urinary fistula to heal.[34] This technique, however, is unlikely to be successful if there is significant ischemic necrosis of the ureter, in which case, surgery still has a role. Reexploration of kidney transplants is straightforward in the early postoperative period but may be a considerable challenge later because of the development of an intense peritransplant fibrotic reaction. The choice of operative procedure for a necrotic distal ureter depends on the length of remaining viable ureter. If there is sufficient length after excision of the necrotic distal portion, the transplanted ureter may simply be reimplanted into the bladder. If this is not possible, the urinary tract should be reconstructed with use of the patient's native ureter. Depending on length of viable transplanted ureter, there is a choice between anastomosing the native ureter to the transplanted ureter proximal to the ischemic segment (ureteroureterostomy) or to the transplanted renal pelvis (ureteropyelostomy; Fig. 103-9). Whichever technique is chosen, the anastomosis should be protected with a double-J stent. Although these techniques require the native ureter to be ligated proximally, there is usually no need to perform an ipsilateral nephrectomy.[35] Postoperatively, the antegrade nephrostomy can be left *in situ* so that a contrast study can be performed after 7 to 10 days to confirm healing of the new anastomosis. If the transplant recipient has undergone an ipsilateral nephrectomy in the past or the native ureter is too diseased to be used for reconstruction, a Boari bladder flap can be used to reconstruct the urinary tract.

Ureteral Obstruction

Obstruction of the transplanted ureter may occur at any time after transplantation. It should always be considered in the differential

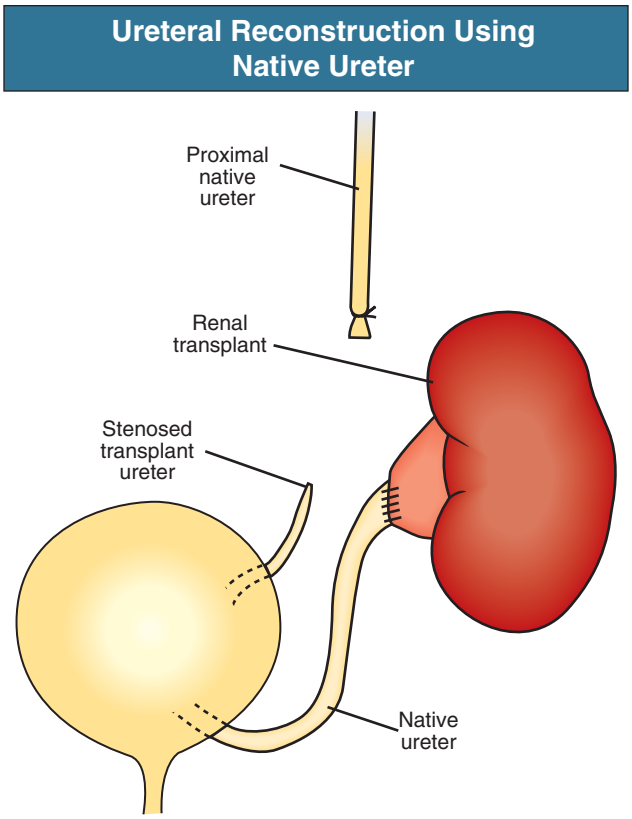

Figure 103-9 **Ureteral reconstruction using native ureter.**

diagnosis of acute transplant dysfunction and excluded by ultrasound examination. The management of transplant ureteral obstruction is summarized in Figure 103-10. Early obstruction is uncommon and suggestive of a technical error, such as creating a submucosal bladder tunnel that is too tight, kinking of a redundant length of ureter, and incorrect suture placement during anastomosis. Early obstruction may also be caused by blood clot in the ureter, bladder, or catheter. Bleeding may occur from the ureterovesical anastomosis or cystostomy or after a transplant biopsy. It is common practice to drain the urinary bladder using a three-way irrigating catheter because small-diameter two-way Foley catheters are easily blocked by blood clot.

Late ureteral obstruction may occur at the vesicoureteral or pelviureteral junctions. Ischemia that is not severe enough to cause necrosis is presumed to be the cause of most vesicoureteral obstructions.[36] Renal transplants invariably excite a pronounced perigraft fibrotic response, and this is more likely to be the cause of an obstruction at the level of the pelviureteral junction. It is also possible that acute rejection episodes contribute to subsequent fibrosis.[34] BK polyoma virus can also cause late ureteric obstruction because of hypertrophy of ureteric epithelial cells in combination with infiltration of inflammatory cells.

An ultrasound scan will demonstrate a dilated pelvicaliceal system. However, longstanding kidney transplants may have quite marked pelvicaliceal dilation without being obstructed. This most commonly causes uncertainty in assessment of whether obstruction may be contributing to chronic allograft dysfunction in a patient with biopsy-proven chronic allograft nephropathy. Further investigation is needed to confirm or refute the presence of obstruction and

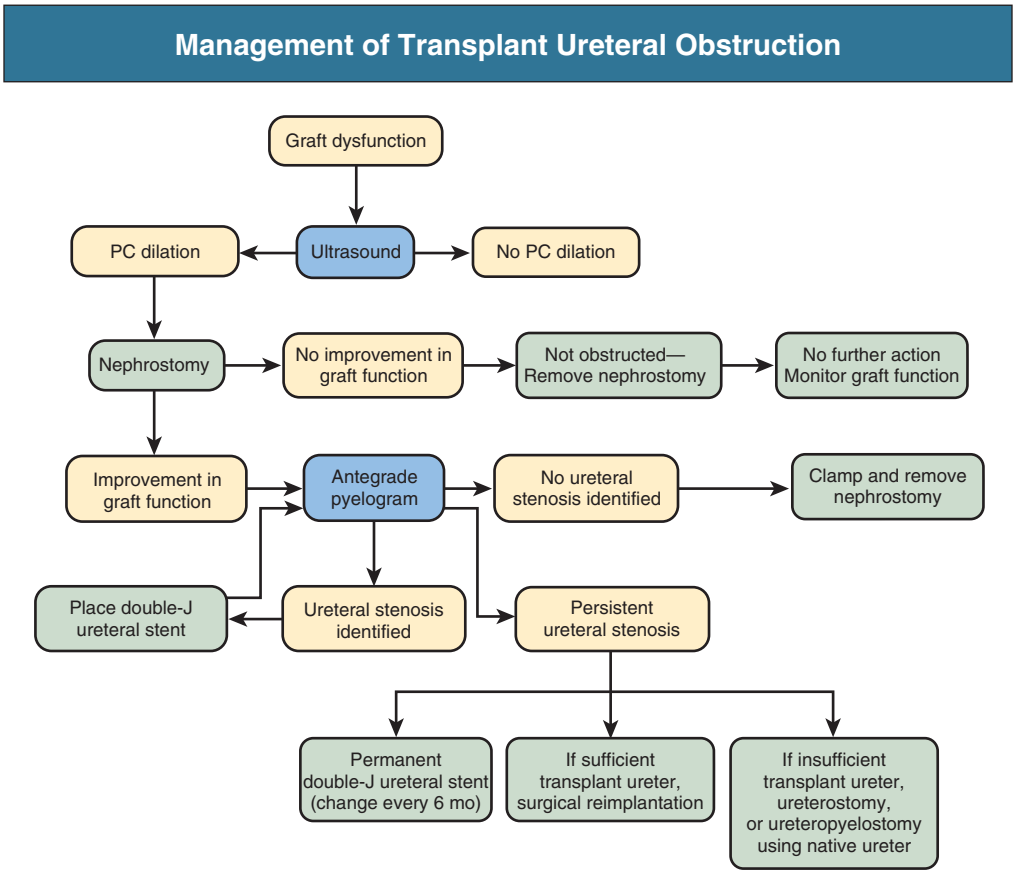

Figure 103-10 **Management of transplant ureteral obstruction.** *PC,* Pelvicaliceal.

to define its anatomy. Retrograde pyelography has a low success rate because of the difficulty of catheterizing the transplanted ureteral orifice at cystoscopy. Therefore, percutaneous nephrostomy followed by antegrade pyelography is the investigation of choice in suspected transplant ureteral obstruction. The nephrostomy is performed under antibiotic cover using ultrasound control, and the nephrostomy tube should be left in place for a few days. If serum creatinine decreases during this period, then obstruction is confirmed. If there is no improvement in renal function, significant obstruction can be confidently excluded. This simple observation avoids the need for an antegrade pressure study (Whittaker test), which may be difficult to interpret in transplanted kidneys. After external decompression of the transplanted kidney for a few days, an antegrade pyelogram is obtained to accurately define the anatomy of the obstructing lesion.

Nonoperative approaches for the treatment of transplant ureteral stricture are often preferred.[37] The simplest approach is to place a double-J stent across the stricture via a percutaneous nephrostomy. This may require initial balloon dilation.[38] The stent can be removed after 6 weeks, but the restenosis rate is high. An alternative is long-term stenting, changing the stent every 6 months. The disadvantage of this method is a high incidence of urinary tract infection, with potential severe consequences for immunosuppressed patients, and long-term antibiotic prophylaxis is a sensible precaution. Open surgical management still has a place in the management of ureteral obstruction. The operation performed depends on the site of obstruction and the remaining length of healthy transplanted ureter proximal to the obstruction (see the discussion of urinary leaks). Not all cases of obstruction require intervention. When there is a mild degree of obstruction not associated with urinary tract infection and in a longstanding kidney that is affected by chronic allograft nephropathy, it may be better to simply monitor transplant function, reserving intervention for a later date should it become necessary.

Complications in the Transplant Bed

A number of nerves may be encountered in the retroperitoneal dissection required for kidney transplantation. These include the lateral femoral cutaneous nerve and the femoral, obturator, and sacral nerves. Each of these may be damaged by a traction injury, particularly when modern fixed wound retraction systems are used, because these can exert a great deal of pressure on the surrounding tissues. Patients with such neurapraxias should recover completely, but this may take some months, and the condition can be very disabling.

In male transplant recipients, the spermatic cord must be mobilized during the dissection to gain access to the retroperitoneal space. Damage to the testicular artery in the cord can result in testicular atrophy.

TRANSPLANT NEPHRECTOMY

The optimal management strategy for patients with a failed renal transplant remains unclear, with a lack of good-quality evidence. Transplant nephrectomy is mandatory for early graft failure caused by vascular thrombosis, capsular rupture, and irreversible rejection. However, the management of a renal transplant that has chronically failed is more challenging. The options are transplant nephrectomy or leaving the graft *in situ,* with or without continuation of immunosuppression. Mortality from both infection and cardiovascular disease have been shown to be higher in patients with failed grafts continuing immunosuppression.[39] However, weaning and discontinuation of immunosuppression have also been shown to increase the risk of transplant nephrectomy and allosensitization.[40]

If the graft remains *in situ* without immunosuppression, signs and symptoms such as pain, fever, hematuria, and thrombocytopenia may prompt transplant nephrectomy, although the patient can also be treated initially with corticosteroids.

Historically, transplant nephrectomy was advocated to remove antigenic stimulation for anti–human leukocyte antigen (HLA) antibody production, which might adversely affect the possibility of retransplantation. However, there is some evidence that transplant nephrectomy, particularly late after transplantation, may actually increase allosensitization.[41] The suggestion is that the graft may act as an "immunologic sponge" to absorb antibody or may regulate the production of antidonor antibody by the recipient's immune system.

Early graft nephrectomy is straightforward, but after the first few weeks kidney transplants usually develop quite intense perigraft fibrosis, and this can make late allograft nephrectomy a difficult technical challenge. A subcapsular dissection is preferred, and after removal of the kidney, the hilum is sutured, leaving a cuff of donor vessels in place. Careful hemostasis is required, and the whole raw capsular bed should be cauterized. The wound is usually closed without drains.

CHAPTER 104

Prophylaxis and Treatment of Kidney Transplant Rejection

Alexander C. Wiseman and James E. Cooper

The clinical presentation of the immune response to transplanted tissue, referred to as *rejection,* became apparent in 1960 when, after successful proof-of-principle kidney transplants were performed in identical twins, kidney transplantation was attempted between immunologically dissimilar individuals.[1] Eleven patients underwent lymphoid irradiation to prevent rejection after kidney transplant from nonidentical donors. Although 10 of the 11 died of overwhelming infection, illustrating the potential consequences of immunosuppression, the lone surviving patient from this series subsequently underwent two episodes of acute rejection, both of which were successfully treated with corticosteroids with successful graft function. Thus began the development of immunosuppressive agents that could prevent and treat rejection while not inducing severe life-threatening side effects, and the characterization of the histologic patterns of injury that quantify the type and severity of rejection. The occurrence of acute rejection in the first year after transplant has significantly diminished from a near-universal occurrence of rejection in earlier eras to present-day rates of 10% to 15%,[2] primarily because of the development of newer immunosuppression medications. Although the incidence of acute rejection has diminished, the management of chronic rejection has remained a challenge, with continued attempts to better define the nature of injury and methods to prevent or reverse this process (Fig. 104-1). However, as attention shifts to limiting the toxicity of immunosuppression medications in corticosteroid-withdrawal and calcineurin inhibitor (CNI)–withdrawal protocols and to attempting to increase access to transplant by performing transplants across human leukocyte antigen (HLA) and blood type barriers, management of acute rejection continues to be an important clinical issue.

DEFINITION

Rejection (both acute and chronic) is defined by histologic findings after kidney transplant biopsy. A biopsy considered adequate for analysis involves sampling of at least 10 glomeruli and two small arteries, stained with hematoxylin-eosin (HE), periodic acid–Schiff (PAS) or silver, and trichrome stains; a biopsy with seven to nine glomeruli and one artery is considered of marginal adequacy. When biopsy is performed for clinical indications (renal dysfunction), two separates cores should be obtained because the findings of rejection are often patchy in distribution (Fig. 104-2).[3] There is not a consensus of opinion regarding the number of cores required when biopsies are performed for nonclinical indications (e.g., in protocol-driven practice), although adequate tissue sampling defined by the previously described criteria is preferable if performed.

The Banff Working Classification of Renal Allograft Pathology forms the basis of the histologic definition of rejection and is continually reviewed and updated on a biannual basis. First developed in 1993 with a primary focus on T cell–mediated acute inflammatory infiltrates to classify the degree of rejection, a more recent (2007) classification now differentiates a humoral (antibody-mediated) response from the T cell response and further distinguishes a chronic humoral form of injury previously included within the term "chronic allograft nephropathy" (see Chapter 107)[4] (Box 104-1). This was based on the indirect identification of antibody-mediated injury via evidence of complement (C4d) deposition. C4d is a fragment of C4b that is generated on IgG and IgM deposition and activation of the classical complement pathway. C4b/C4d forms a covalent bond with proteins on tissue such as capillary endothelial cells via a sulfhydryl group, and persists bound to tissue after immunoglobulin and other complement products have been released.[5] Staining for C4d, either by immunohistochemistry or immunofluorescence, is often performed on allograft biopsy specimens to aid in identifying if an antibody-mediated process may be involved in patients with graft dysfunction. Although issues of standardization and reliability of staining exist, C4d staining remains an important marker of antibody-mediated injury and should be performed in any biopsy from which a change in immunosuppression may be entertained.

Antibody-Mediated Rejection

Acute antibody-mediated (humoral) rejection (AHR) is estimated to occur in 3% to 10% of all transplants and is present in 20% to 30% of episodes of acute rejection,[6] occurring typically within the first few weeks of transplantation or in association with a change in immunosuppression. Although patients who have pre-existing donor-specific HLA alloantibodies ("donor-specific antibodies") are at higher risk for the development of acute humoral rejection, the identification of *de novo* donor-specific antibodies at the time of graft dysfunction is common. The diagnosis of acute humoral rejection requires (a) evidence of circulating donor-specific antibodies, (b) C4d deposition in peritubular capillaries, and (c) evidence of tissue injury (Fig. 104-3). Patterns of injury associated with acute humoral rejection range from acute tubular cell injury suggestive of acute tubular necrosis to thrombotic microangiopathy (TMA), but typically will be associated with neutrophils and/or macrophages in peritubular capillaries. Staining for C4d is considered a sensitive marker for acute antibody-mediated injury and should be routinely performed on renal allograft biopsy specimens when this process is being considered in the differential diagnosis.

Chronic active antibody-mediated rejection has been identified as a leading cause of late allograft loss,[7,8] and accurately diagnosing this condition has been a subject of interest. Chronic active antibody-mediated rejection is likely the result of an indolent alloimmune response that can result in transplant glomerulopathy and microcirculatory inflammation (Fig. 104-4). Although transplant glomerulopathy is often associated with circulating donor-specific antibodies

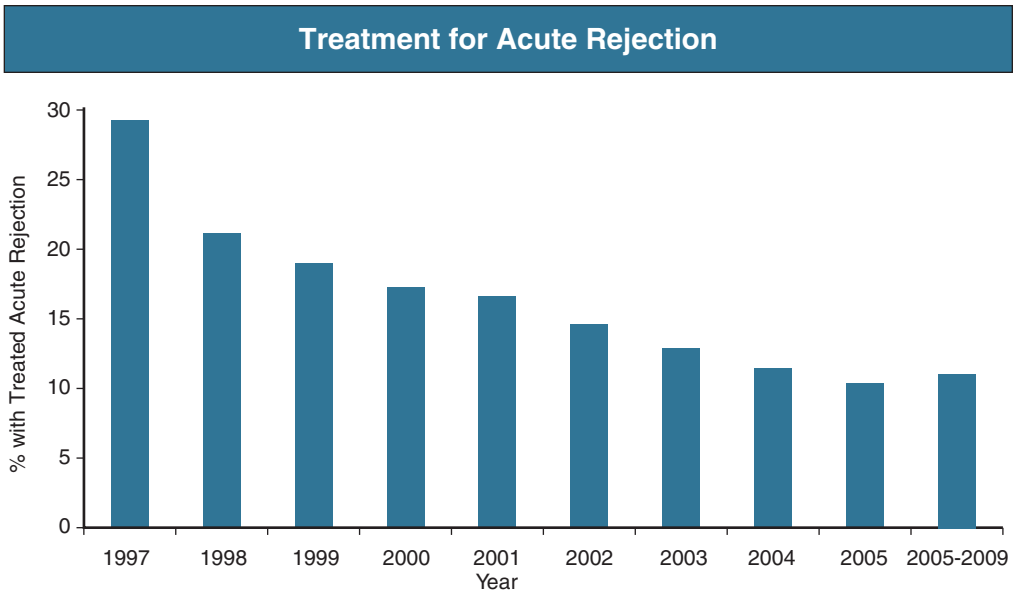

Figure 104-1 Treatment for acute rejection for all kidney transplants in the United States, 1997-2005. (As reported to the Scientific Registry of Transplant Recipients, SRTR reports 2007 and 2012.)

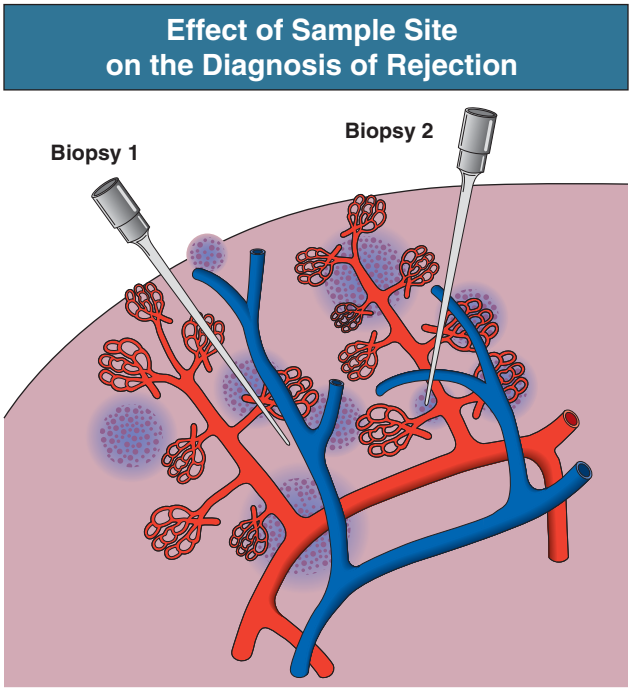

Figure 104-2 Effect of sample site on the diagnosis of rejection. Acute rejection begins as patchy, focal infiltrates and becomes homogeneous only in advanced stages. The intensity of mononuclear infiltrate seen on biopsy would differ between core 1 and core 2. Routinely taking two core biopsy samples can help decrease the sampling errors, which can affect the histologic interpretation of rejection.

BANFF Classification of Rejection

Antibody Mediated

Acute

C4d$^+$, presence of circulating antidonor antibodies and acute tissue injury

I. ATN-like (minimal inflammation)

II. Capillary and/or glomerular inflammation and/or thromboses

III. Arterial inflammation

Chronic

C4d$^+$, presence of circulating antidonor antibodies and chronic tissue injury
(1) Glomerular double contours, (2) peritubular capillary basement membrane multilayering, (3) tubular atrophy or interstitial fibrosis, and/or (4) fibrous intimal thickening in arteries

T Cell Mediated

Acute

Mononuclear cell interstitial inflammation and tubulitis and/or arteritis

IA: More than 25% interstitial infiltration, 4 to 10 mononuclear cells/tubular cross section

IB: More than 25% interstitial infiltration, >10 mononuclear cells/tubular cross section

IIA: Intimal arteritis, mild to moderate (0% to 25% of luminal area)

IIB: Intimal arteritis, severe (>25% of luminal area)

III: Transmural arteritis and/or fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocyte inflammation

Chronic

Arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neointima

Borderline

Presence of 10% to 25% interstitial infiltration, <4 mononuclear cells/tubular cross section

Box 104-1 Classification of rejection. *ATN,* Acute tubular necrosis. *(Modified from reference 4.)*

and C4d deposition, 30% to 50% of cases will be identified in the absence of these diagnostic markers.[9] This suggests that either these lesions are not solely caused by a humoral response or the lack of a temporal relationship of donor-specific antibodies or C4d deposition to biopsy findings is related to phenomena such as non–complement fixing antibodies and/or the waxing-waning nature of the humoral response.

The current Banff diagnostic criteria for chronic humoral rejection require (1) evidence of donor-specific antibodies, (2) C4d deposition in peritubular capillaries, and (3) evidence of chronic tissue

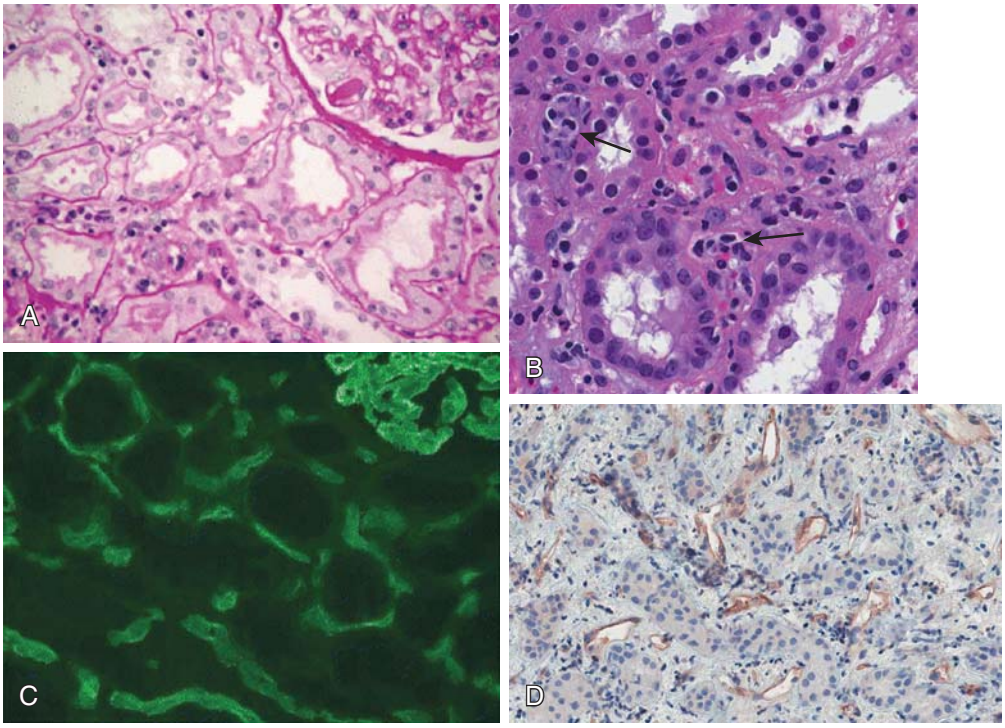

Figure 104-3 Acute antibody-mediated rejection. A, Peritubular and glomerular capillaries contain numerous polymorphonuclear leukocytes and mononuclear cells. **B,** Numerous polymorphonuclear leukocytes are observed in a peritubular capillary *(arrows)*. Interstitial edema is noted. (Periodic acid–Schiff; magnification ×200.) **C,** Immunofluorescence staining of peritubular capillaries with C4d. Figure 104-4 Transplant glomerulopathy. Light microscopy showing typical membranoproliferative changes, including glomerular basement membrane duplication and thickening *(arrows)*.

injury. The forms of chronic tissue injury may include duplication of the glomerular basement membrane, multilamination of the peritubular capillary basement membrane, arterial intimal fibrosis without elastosis, and/or interstitial fibrosis with tubular atrophy. Although the Banff classification still recognizes diffuse peritubular capillary C4d deposition as a diagnostic criterion for chronic active antibody-mediated rejection, recent evidence questions the sensitivity of C4d in detecting humoral graft damage and suggests that microcirculatory injury (peritubular capillaritis, glomerulitis) may be a more important indicator of this process.[7,10] Recent molecular studies show upregulated endothelial gene expression in combination with circulating donor-specific antibodies to be indicative of antibody-mediated graft damage (termed *C4d-negative antibody-mediated rejection*) and a more sensitive indicator of graft loss than C4d deposition.[11] A report from the 2011 Banff meeting recognizes the existence of C4d-negative antibody-mediated rejection and has aimed to define diagnostic criteria for this entity.[12]

T Cell–Mediated Rejection

The classical pathologic description of rejection is now referred to as *T cell–mediated rejection.* The classification of acute T cell–mediated rejection (acute cellular rejection [ACR]) is based on the degree and location of mononuclear cell inflammation. Because interstitial inflammation and tubulitis are frequently present immediately beneath the renal capsule (subcapsular inflammation) in stable allografts, this histology is not taken into account in interpreting an allograft biopsy for the presence of rejection. When severe, interstitial inflammation may extend into tubules via injury to the tubular basement membrane (tubulitis). The predominant phenotype of these infiltrates is a mixture of $CD4^+$ and $CD8^+$ T cells; however, B cells, eosinophils, and macrophages may also be present. Less commonly, endarteritis (endothelialitis) may be present: T cells and macrophages extend under the arterial endothelium, a phenomenon that may or may not be accompanied by interstitial inflammation or tubulitis. The finding of interstitial infiltrates and tubulitis in a kidney transplant biopsy specimen is not specific to ACR, and other causes such as viral nephropathy (BK virus, less commonly cytomegalovirus [CMV]), pyelonephritis, or post-transplant lymphoproliferative disease should be considered based on the clinical presentation. In contrast, the histologic finding of endothelialitis is pathognomonic of ACR.

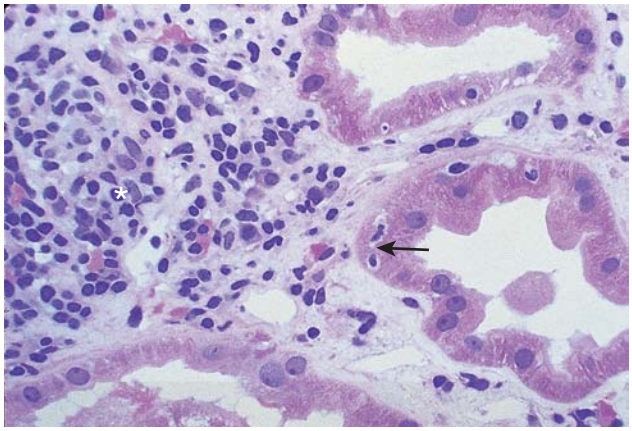

Figure 104-5 Type I acute cellular rejection. Type I acute rejection manifests with interstitial mononuclear cell infiltration *(asterisk)* with invasion of the tubules *(arrow).* (Periodic acid–Schiff; magnification ×200.)

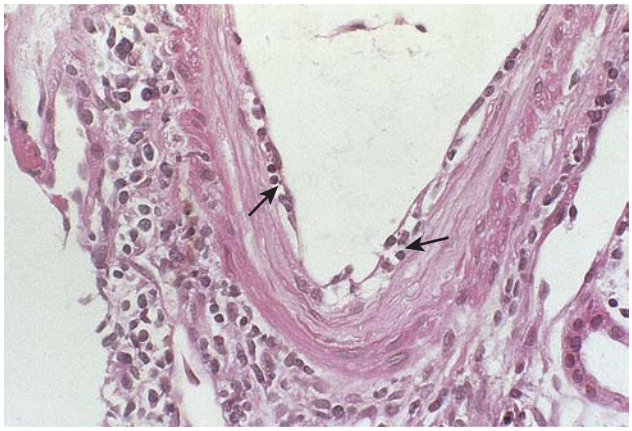

Figure 104-6 Type II acute cellular rejection. Type II rejection, called *acute vascular rejection,* manifests with endothelialitis with mononuclear cell infiltration *(arrows)* beneath the arterial endothelium. (Periodic acid–Schiff; magnification ×200.) *(Courtesy Dr. Agnes Fogo, Vanderbilt University, Nashville, Tennessee.)*

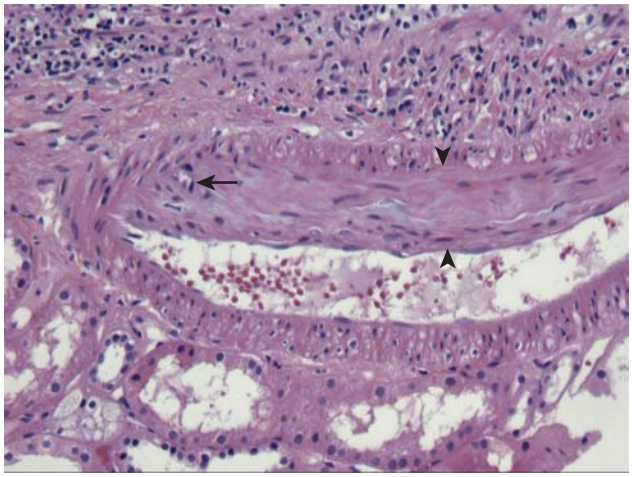

Figure 104-8 Chronic active T cell–mediated rejection. Chronic allograft arteriopathy with the formation of a fibrous neointima *(between arrowheads)* and embedded mononuclear cell infiltration *(arrow).* (Hematoxylin-eosin stain; magnification ×200.) *(Photomicrographs courtesy Dr. Maxwell Smith, University of Colorado, Denver, Colorado.)*

Acute T cell–mediated rejection is histologically classified in the Banff criteria based on the presence or absence of endothelialitis, the degree of interstitial inflammation, and the quantity of infiltrating cells into tubules. Type I ACR is characterized by the absence of endothelialitis, with interstitial inflammation of at least 25% of the parenchyma, and tubulitis (type IA requires 4 to 10 mononuclear cells/tubular cross section, whereas type IB requires >10 mononuclear cells/tubular cross section) (Fig. 104-5). Type II ACR is characterized by vascular involvement or endothelialitis (IIA requires mild to moderate intimal arteritis, and IIB requires arteritis with at least 25% of the luminal area lost in at least one arterial cross section) (Fig. 104-6). Type III ACR is characterized by vascular inflammation that extends to the media ("transmural") and may be accompanied by fibrinoid change and necrosis of the smooth muscle cells (Fig. 104-7). Type II and III ACR may or may not be associated with elements of type I ACR; therefore the pathologic description of rejection should not be viewed as a pathogenic continuum. However, type II and III ACR appear to require different therapeutic interventions and carry different prognostic implications than type I ACR (see later sections).

Chronic active T cell–mediated rejection is a histologic diagnosis that refers to arterial intimal fibrosis specifically with evidence of mononuclear cell infiltration and formation of neointima (Fig. 104-8). This is distinguished from chronic humoral rejection by the location of vascular injury and lack of evidence of pathogenic antibody, and is distinguished from other nonimmunologic processes that may lead to vascular and interstitial fibrosis by the presence of persistent infiltrating cells within vessels. This is covered in greater detail in Chapter 107.

Borderline Rejection

The finding of inflammation in 10% to 25% of the interstitium with tubulitis of less than four mononuclear cells per tubular cross section is classified as borderline rejection. This currently remains a pathologic definition without clear clinical significance. When borderline rejection is identified in the setting of graft dysfunction or with other findings such as glomerulitis, the risk of progression to clinical rejection on subsequent biopsies is increased and therefore treatment may be considered.[13]

Differential Diagnosis of Renal Allograft Dysfunction

Week 1 Post-Transplantation
Acute tubular necrosis
Hyperacute or accelerated rejection
Urologic
  Obstruction
  Urine leak
Vascular thrombosis
  Renal artery
  Renal vein
Volume contraction

<12 Weeks After Transplantation
Acute rejection
Calcineurin inhibitor toxicity
Volume contraction
Urologic
  Obstruction
Infection
  Bacterial pyelonephritis
  Viral infections
Interstitial nephritis
Recurrent disease

>12 Weeks After Transplantation
Acute rejection
Volume contraction
Calcineurin inhibitor toxicity
Urologic
  Obstruction
Infection
  Bacterial pyelonephritis
  Viral infections
Chronic allograft nephropathy
Recurrent disease
Renal artery stenosis
Post-transplantation lymphoproliferative disorder

Box 104-2 Differential diagnosis of renal allograft dysfunction.

CLINICAL MANIFESTATIONS

The clinical presentation of acute rejection is common to both T cell and antibody-mediated rejection. Patients typically present with a rapid rise in serum creatinine, and in severe cases may have a decreasing urine output, weight gain, fever, or graft tenderness. The clinical findings are commonly nonspecific, and other causes of graft dysfunction are often considered at the time of presentation in the context of an individual's risk for the development of acute rejection (Boxes 104-2 and 104-3). Because of the increase in presensitized patients undergoing transplantation, patients with known donor-specific antibody in desensitization protocols, and ABO-incompatible transplants, approximately 25% of acute rejection episodes now have a humoral component. In acute humoral rejection there may be features of TMA with microangiopathic anemia and thrombocytopenia. If there is immediate cyanosis of the graft on revascularization (hyperacute rejection) or an abrupt decline in urine output and graft tenderness 3 to 14 days post-transplant (delayed hyperacute or accelerated rejection), donor-specific antibody is implicated. Typically there is type III AHR and interstitial hemorrhage on biopsy.

Risk Factors for Acute Rejection

High Risk
Sensitization (high panel reactive antibody percentage)
  Previous transplantation
  Pregnancy
  Transfusion
Delayed graft function
  Deceased donor source
  Increased donor age
  Prolonged ischemic time
  Donor brain death
  Donor acute renal dysfunction
HLA mismatching
Positive pretransplantation B cell crossmatch
ABO incompatibility
Corticosteroid minimization
Infection
  Bacterial pyelonephritis
  Cytomegalovirus
Adolescent recipient
African American recipient
Previous rejection episode

Low Risk
Zero HLA mismatch
Elderly recipient of young donor kidney
Preemptive transplantation
Living donor source
First transplant

Box 104-3 Risk factors for acute rejection. *HLA,* Human leukocyte antigen.

PROPHYLAXIS AND PREVENTION

Prophylaxis

The primary goal of transplant management is prevention of immunologic graft loss in the early period after transplant. Over time, the risk for acute rejection diminishes and goals of immunosuppression therapy shift toward considerations of side effects of medications and risks for other events such as cardiovascular disease and malignancy. Therefore, current clinical practice follows a general strategy of intensive immunosuppression and monitoring in the first months after transplant with a reduction or alteration of treatment after the initial period of risk.

Prevention of Acute T Cell–Mediated Rejection: Induction Therapy

The use of a brief course of potent immunosuppression at the time of transplant, referred to as *induction therapy,* has become a common strategy for the prevention of acute rejection in all transplant recipients including both those at higher and lower immunologic risk. According to the Scientific Registry of Transplant Recipients (SRTR), 83% of kidney transplant recipients received induction therapy in the United States in 2011. For higher-risk patients such as those with prior sensitization (the presence of HLA antibodies quantified by percent reactivity against a panel of common HLA types, referred to as percent panel reactive antibody [PRA]), prior transplant, or African American ethnicity, induction therapy is usually combined

with standard doses of immunosuppression to prevent rejection. For those with lower risk (living donor kidney recipients, primary kidney transplants), induction therapy is often used in an effort to minimize exposure to maintenance immunosuppression. The use of race as a risk factor for rejection has recently been questioned with a study demonstrating similar acute rejection rates in African Europeans compared with European Caucasians in France.[14] However, most studies still report a higher risk of rejection for African Americans than American Caucasians; thus induction therapy is commonly used in this population.[15]

Induction agents can be classified as T cell depleting or nondepleting. Nondepleting agents include the monoclonal humanized interleukin (IL)–2 receptor antibody (IL-2Ra) agent daclizumab (no longer available for use because of manufacturer withdrawal) and the chimeric agent basiliximab. The IL-2 receptor was identified as a potential immunosuppressive target because it is present on T cells and because inhibition of IL-2/IL-2R signaling inhibits T cell proliferation (see Chapter 101). Use of IL-2Ra has resulted in a reduction in acute rejection rates with minimal side effects when combined with cyclosporine-based immunosuppression in the absence of mycophenolate.[16] It is important to note that these agents have not been studied in a prospective randomized fashion in combination with a tacrolimus-mycophenolate–based maintenance regimen; therefore questions still remain regarding the relative benefits of the addition of IL-2Ra with more potent, commonly used maintenance agents.[17]

Depleting agents include antithymocyte globulin, OKT3, and anti-CD52. Unlike the IL-2Ra agents, none of these agents have been compared with placebo for the prevention of rejection, and thus their use as induction agents is considered off-label in the United States. Antithymocyte globulin is a polyclonal preparation of antibodies directed at T cells prepared by immunizing animals with human lymphoid cells derived from the thymus. An antithymocyte preparation created from equine sources was shown to be inferior to other depleting agents in the treatment of rejection, and its use has diminished.[18] Currently, the most common antilymphocyte preparation in use is rabbit antithymocyte globulin (rATG). Anti-CD3 (OKT3), a mouse monoclonal antibody directed to the CD3 subunit of the T cell receptor, also results in depletion of T cells but also is associated with a significant innate immune response to foreign antibody that results in a cytokine release syndrome that presents with fevers, hemodynamic changes, pulmonary edema, and, less commonly, seizure and is no longer manufactured. Recently the use of anti-CD52 (alemtuzumab) has increased in kidney transplantation. This agent binds to CD52, an antigen of unclear physiologic significance that is present on both B and T cells, and results in depletion of both lymphoid cell lines. Its ability to induce prolonged, significant lymphopenia for up to 6 to 12 months after administration led to its use in refractory chronic lymphocytic leukemia. Unlike other depleting agents, it is a humanized antibody and therefore has fewer infusion-related side effects than either rATG or OKT3. Initial trials suggest equivalence to other depleting agents in the prevention of rejection, but the long-term impact of prolonged lymphopenia on the risk for infection or post-transplant lymphoproliferative disorder has yet to be determined, and comparative trials of induction agents are lacking (see later).

Although effective in the inhibition of the T cell response, all depleting agents raise concerns regarding long-term safety. Registry analyses suggest that there is an increased risk of future development of lymphoma with depleting agents compared with nondepleting agents or no induction therapy,[19-20] an association that appears to be dose dependent. For this reason, repeated or prolonged courses of depleting antibody therapy must be considered with this risk balanced by the potential for graft recovery or prolongation.

Three multicenter randomized trials have compared the efficacy of induction agents in the prevention of acute rejection. A multicenter trial in patients at high risk for acute rejection (defined as recipients with an elevated risk of delayed graft function, elevated PRA, repeat transplants, or HLA mismatches) compared the IL-2Ra basiliximab with rATG with maintenance immunosuppression of cyclosporine, mycophenolate mofetil (MMF), and prednisone.[21] At 12 months, the rate of acute rejection in the basiliximab cohort was 26% versus 16% in the rATG arm. A second trial in patients at high risk for acute rejection (defined by elevated PRA screening result, repeat transplants, or loss of a previous kidney transplant to acute rejection) compared the IL-2Ra daclizumab with rATG, with remarkably similar findings of increased rejection incidence for patients randomized to daclizumab (27%) compared with rATG (15%) at 1 year.[22] Thus, for patients at increased risk for rejection, rATG provided greater prevention of acute rejection, supporting its use in higher-risk populations. Finally, a clinical trial compared anti-CD52 either with rATG in high-risk patients (repeat transplant, elevated PRA, or African American race) or with an IL-2Ra in low-risk patients, followed by early corticosteroid withdrawal and maintenance tacrolimus and mycophenolate immunosuppression.[23] The 12-month acute rejection rates in the high-risk arms were 10% for anti-CD52 and 13% for rATG, and in the low-risk arms were 20% for IL-2Ra and 3% for anti-CD52, suggesting a therapeutic benefit of anti-CD52 over IL-2Ra in the low immunologic risk population. Between 12 and 36 months, however, acute rejection rates in anti-CD52 treated patients were higher in both low- and high-risk arms, suggesting a delayed (>12 month) immunologic risk of immune reconstitution with anti-CD52 therapy. This may be problematic for transplant care providers who generally adhere to less rigorous late (>12 month) clinical monitoring protocols for otherwise stable transplant recipients. In general, the issue of the need for induction therapy in low-risk patients is not fully resolved and requires further prospective head-to-head trials, whereas patients at higher immunologic risk appear to benefit from lymphocyte depleting treatment. Common dosage regimens of induction agents are listed in Table 104-1.

Prevention of Acute Antibody-Mediated Rejection: Desensitization

The patient who has donor-specific antibodies or is blood type incompatible with the donor before transplant has a near-universal risk of developing acute antibody-mediated rejection after transplant without pretransplant therapeutic intervention. "Desensitization" protocols may permit transplantation of these donor-recipient combinations. Desensitization protocols typically involve removal of preformed antibody with plasma exchange and/or suppression of antibody production and action with intravenous immunoglobulin (IVIG) or B cell inhibition with rituximab. Several different desensitization strategies were adopted by transplant centers over the previous decade and are generally influenced by factors such as type of transplant (living vs. deceased donor) and the degree of HLA-antibody reactivity that one is attempting to overcome. In the case of living donation the crossmatch barriers are known in advance, allowing for protocols of plasma exchange followed by low-dose (100-200 mg/kg) IVIG to be used and transplant to be pursued when the desired crossmatch results are obtained. Protocols consisting of monthly high-dose IVIG (1 to 2 g/kg) infusions with or without rituximab[24] have been used in situations where pretransplant plasma exchange is not feasible, such as in sensitized patients without living donor options awaiting deceased donor kidneys.

Agents Used for Induction and Treatment of T Cell–Mediated Rejection			
Agent	**Target**	**Dose (Induction)**	**Dose (Rejection)**
Methylprednisolone	B cells, T cells, macrophages	500 mg IV intraoperatively, followed by taper over 1 to 5 days	3-5 mg/kg (250-500 mg) IV × 3-5 days
Basiliximab	IL-2 receptors on cells	20 mg IV × 2 on days 0, 4	N/A
Daclizumab	IL-2 receptors on cells	1-2 mg/kg IV every 2 weeks for five doses after transplantation	N/A
OKT3	CD3 on T cells	5 mg IV × 7-14 days	5 mg IV × 7-14 days
rATG	T cell surface antigens	1-1.5 mg/kg IV × 4-14 days	1-1.5 mg/kg IV × 7-14 days
Anti-CD52	CD52 on T and B cells	30-60 mg × 1 or 2 on days 0 and 2	Same as induction

Table 104-1 Agents used for induction and treatment of T cell–mediated rejection. *IL,* Interleukin; *IV,* intravenously; *NA,* not applicable; *rATG,* rabbit antithymocyte globulin.

Agents Used for Desensitization and Treatment of Antibody-Mediated Rejection			
Treatment	**Mechanism**	**Protocol (Desensitization)**	**Dose (Antibody-Mediated Rejection)**
Plasma exchange	Antibody removal	Two to four sessions or until XM acceptable, combined with IVIG	Two to five treatments, daily or every other day, combined with IVIG
IVIG	Multiple, antibody inhibition?	100-200 mg/kg after plasma exchange until acceptable XM *or* 1-2 g/kg monthly until transplant	100-200 mg/kg after plasma exchange
Rituximab	Anti-CD20 B cell inhibition	375 mg/m^2 (day 15) combined with IVIG 1-2 g/kg (days 1 and 30)	375 mg/m^2 with plasma exchange and IVIG
Bortezomib	Plasma cell inhibition	Not established	1.3 mg/m^2 × four doses over 1-2 weeks, usually combined with plasma exchange and IVIG
Eculizumab	Terminal complement C5 inhibition	Not established	For prevention in +XM transplant: 600-1200 mg weekly × 4 then biweekly until successful antibody reduction
Splenectomy	B cell removal	No longer used	N/A, for severe refractory cases only

Table 104-2 Agents used for Desensitization and Treatment of Antibody-Mediated Rejection. *IVIG,* Intravenous immunoglobulin; *N/A,* not applicable; *+XM,* positive crossmatch.

Desensitization strategies have allowed for transplantation to occur for sensitized patients who otherwise may not be afforded the opportunity. In return, however, these procedures are generally met with high rates of acute rejection, ranging from 20% to 70% (depending on a variety of factors including specific protocol, induction immunosuppression, and immunologic risk), are often humoral in nature, and frequently progress to chronic antibody-mediated injury.[25-26] Despite these pitfalls, short-term graft survival after desensitization has been acceptable,[25] and data suggest a survival benefit out to 8 years for desensitized patients undergoing transplant compared with matched controls undergoing dialysis while on the waiting list.[27] Thus HLA desensitization for highly sensitized transplant candidates may be a reasonable option, and referral to a transplant center with experience in this field is warranted. Common desensitization agents and protocols are listed in Table 104-2.

Maintenance Therapy for the Prevention of Acute Rejection

Current maintenance immunosuppression most commonly includes a CNI, an antiproliferative agent, and corticosteroids. This combination of agents forms the standard against which novel strategies are compared, such as corticosteroid withdrawal and avoidance and CNI withdrawal and avoidance. Cyclosporine has been replaced by tacrolimus as the preferred CNI in the United States and, together with the antiproliferative agent MMF, forms the most common immunosuppressive regimen in current practice in the United States and most Western countries (Table 104-3); cyclosporine and azathioprine remain commonly used agents worldwide.

Immunosuppression Regimens in the United States, 2011	
Induction Regimens at Time of Transplant	
IL-2Ra	20.9%
T cell depleting	58.6%
Maintenance Regimens at Time of Hospital Discharge	
TAC/MMF-MPS/Pred	59.3%
CSA/MMF-MPA/Pred	1.9%
Corticosteroid free (any) TAC/MMF-MPA CSA/MMF-MPS	29.3% 26.3% 0.5%

Calcineurin Inhibitors in the Prevention of Acute Rejection

Since the early 1980s when the introduction of cyclosporine resulted in a reduction in the incidence of acute rejection and improvements

in projected graft survival,[28] calcineurin inhibition has been a cornerstone of maintenance immunosuppression. Tacrolimus, first introduced in the 1990s and compared head-to-head with cyclosporine in a number of trials, appears to provide greater protection from acute rejection but with a different side effect profile. A meta-analysis of trials that compared tacrolimus- and cyclosporine-based immunosuppression demonstrated a reduction in risk of acute rejection of 31% but an increase in risk of development of diabetes of 86%. Tacrolimus was also associated with a better death-censored graft survival (hazard ratio [HR] 0.56), particularly at target trough doses below 10 ng/ml, a finding that was not shown in individual studies.[29]

Antiproliferative Agents in the Prevention of Acute Rejection

The first antiproliferative agent used in kidney transplantation, azathioprine, was introduced in the early 1960s and was used initially in conjunction with corticosteroids and later with cyclosporine. Although its development was critical in the advancement of allotransplantation, acute rejection was quite common, with acute rejection rates of 35% to 40% in a number of clinical trials in which cyclosporine, azathioprine, and prednisone were used. Newer antiproliferative agents emerged in the 1990s (MMF) and later the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus, which significantly reduced the incidence of acute rejection.

Mycophenolate mofetil, a purine antagonist that interferes with DNA synthesis in rapidly dividing cells such as activated lymphocytes, gained popularity after a number of multicenter prospective clinical trials demonstrated an approximately 50% reduction in the incidence of acute rejection compared with azathioprine.[30-31] A large registry analysis suggests that there is a beneficial effect of MMF on graft survival, independent of acute rejection.[32] One drawback of MMF has been gastrointestinal (GI) intolerance, which often results in reduction of therapy with attendant risks of acute rejection[33] and graft loss.[34] An MMF analogue, enteric-coated mycophenolate sodium (EC-MPS), has been developed and appears to be "noninferior" in efficacy to MMF,[35] with fewer GI side effects reported in one open-label study.[36]

Similar to MMF, the mTOR inhibitors sirolimus and everolimus were initially tested in clinical trials as a substitute for azathioprine and demonstrated reductions in acute rejection rates similar to MMF.[37] mTOR inhibitors inhibit the progression from the G_1 to the S phase of the cell cycle and appear to have additional antiproliferative effects on nonimmune cells that may contribute to an increase in side effects (impaired wound healing, lymphocele formation, proteinuria, and slower recovery from delayed graft function) but also may reduce the incidence of viral infection and malignancy.[38-39]

Acute Rejection Rates in Calcineurin Inhibitor– and Corticosteroid-Sparing Immunosuppression Regimens

Given the advances in immunosuppression over the last decade, attempts to eliminate undesirable side effects of immunosuppression have assumed a greater importance in the management of patients. Avoidance of CNIs offers the hope of prolonged graft survival, given the inherent nephrotoxicity of this medication class, whereas avoidance of corticosteroids offers the hope of reducing a number of cosmetic, metabolic, and cardiovascular side effects attributable to prednisone.

Early corticosteroid cessation (within 7 days after transplant) has become increasingly popular in the United States. In 2011 more than 33% of all patients were discharged after transplant without maintenance prednisone therapy. In general, patients at lower immunologic risk (low PRA, first transplants) are selected,[40-41] and immunosuppression includes induction therapy, a CNI, and an antiproliferative agent. Acute rejection rates in single-center studies range from 10% to 15%. In the largest prospective, double-blind, multicenter study of corticosteroid cessation versus standard corticosteroid maintenance to date,[42] a standard corticosteroid taper or a rapid elimination of corticosteroids at 7 days after transplant was compared on the background of induction therapy plus tacrolimus-MMF–based immunosuppression. Patient survival, graft survival, and creatinine clearance were comparable at 5 years. Cardiovascular risk factors and weight gain were not significantly different, but corticosteroid withdrawal was associated with less bone disease, less insulin-requiring new-onset diabetes, and lower triglyceride levels. One cause for concern with corticosteroid withdrawal was that rejection rates were higher in the corticosteroid withdrawal arm (18% vs. 11%, $P = .04$), and a *post hoc* analysis suggested a higher rate of chronic allograft nephropathy in the corticosteroid withdrawal arm. It is unlikely that another study will be performed with this rigor with follow-up for longer than 5 years; therefore clinicians must weigh a higher incidence of rejection versus the potential benefits when counseling patients regarding corticosteroid withdrawal. The study was performed in patients at low immunologic risk without the presence of delayed graft function; therefore consideration for corticosteroid withdrawal is best supported for the patient with a lower expected risk for rejection (low immunologic risk, expected immediate graft function) or high expected risk for corticosteroid-related complications, such as patients with bone disease or diabetes.

Calcineurin inhibitor avoidance has been studied with both dual therapy (MMF and prednisone) and triple therapy with two antiproliferative agents (sirolimus, MMF, and prednisone) in combination with induction therapy. In general, MMF-prednisone maintenance immunosuppression does not appear to be effective in the prevention of rejection (70% incidence in one pilot study[43]), and although single-center studies report acute rejection rates of 6% to 13% with sirolimus-MMF-prednisone therapy,[44-45] a large multicenter trial using this combination and target trough concentrations of sirolimus of 4 to 8 ng/ml also revealed an excessively high acute rejection rate (38%).[46] CNI avoidance was more successful in the Belatacept Evaluation of Nephroprotection and Efficacy as First-Line Immunosuppression Trial (BENEFIT), which compared the costimulation blocker belatacept at two doses with cyclosporine with IL-2Ra induction and mycophenolic acid (MPA)–prednisone maintenance.[47] Despite higher 1-year acute rejection rates in the belatacept arms (22% and 17% for higher and lower intensity, respectively, vs. 7% for cyclosporine), graft survival was comparable and measured glomerular filtration rate (GFR) significantly higher for those receiving belatacept (65 and 63 mL/min for high- and low-intensity belatacept vs. 50 mL/min for cyclosporine). These trends have continued at 3 years of follow-up.[48] Concerning, however, are higher rates of post-transplant lymphoproliferative disorder associated with patients receiving belatacept, primarily in those who received higher-intensity dosages and were Epstein-Barr virus (EBV) seronegative at transplant.

In contrast to their use in complete CNI avoidance strategies, mTOR inhibitors have achieved relative success when used in CNI withdrawal[49-50] and conversion protocols. In one study, patients receiving a CNI, MMF, and prednisone were randomized to continue this regimen or undergo CNI conversion to sirolimus at 1 to 6 months after transplant; rates of acute rejection were comparable and renal function was statistically similar at 2 years.[51] Another study, using a similar approach of CNI conversion to everolimus at 4 to 5 months after transplant, demonstrated equivalent rates of acute

Maintenance Immunosuppression and Reported Rejection Rates in Randomized Multicenter Trials

Regimen	Induction	CNI Dose or Trough Level Goal	Antiproliferative Dosing	Acute Rejection at 6 months
Low Immunologic Risk				
CSA/AZA/Pred		4.0 mg/kg/d	1.5-2 mg/kg/d	36%[26]
CSA/AZA/Pred	IL-2Ra	Not stated	Not stated	22%[14]

Table 104-4 Maintenance immunosuppression and reported rejection rates in randomized multicenter trials. Antiproliferative dosage is shown as SRL trough level goals and for MMF as dose. Mycophenolate trough levels are of limited value. For general comparison only. In comparing acute rejection rates from various clinical trials, the study population and treatment algorithms may be different among trials. *AZA,* Azathioprine; *Bela,* belatacept; *CNI,* calcineurin inhibitor; *CSA,* cyclosporine; *EVL,* everolimus; *IL-2Ra,* interleukin (IL)–2 receptor antibody; *MMF,* mycophenolate mofetil; *N/A,* not applicable; *Pred,* prednisone; *rATG,* rabbit antithymocyte globulin; *SRL,* sirolimus; *TAC,* tacrolimus. *Refers to acute rejection rate at 12 months.

rejection (15% in both groups) and significantly improved estimated glomerular filtration rate (eGFR) at 12 months in the conversion group (72 mL/min vs. 62 mL/min in the CNI continuation arm).[52] Widespread acceptance of CNI to mTOR inhibitor conversion strategies has been hindered because of issues with mTOR inhibitor–related side effects and tolerability as well as reluctance to alter immunosuppression in the otherwise stable transplant recipient.

Acute rejection rates by treatment regimen reported in recent multicenter clinical trials are shown in Table 104-4. These rates are often higher than rates reported to registries (see Fig. 104-1) because of the more rigorous follow-up and mandatory reporting within the context of clinical trials.

TREATMENT

Acute T Cell–Mediated Rejection

Treatment of T cell–mediated acute rejection is often directed by the findings on biopsy and the clinical response to pulse corticosteroids. For the patient with graft dysfunction and biopsy-proven rejection, treatment with intravenous methylprednisolone 3 to 5 mg/kg (250 to 500 mg/d) for 3 to 5 days is often effective if the histologic injury is tubulointerstitial (Banff class IA or IB). Remarkably few studies of the clinical response to corticosteroids in the treatment of acute rejection have been performed under modern immunosuppression, but prior data suggest that 60% to 70% of patients will respond with improved urine output and decreasing serum creatinine within 5 days. If there is inadequate response after corticosteroid pulse therapy or if there is vascular involvement (Banff class IIA, IIB), corticosteroids often must be supplemented with T cell–depleting antibody therapies in a similar dosage strategy but with a longer treatment course when compared with their use for induction (see Table 104-1). Most studies have used these agents in 7- to 14-day treatment courses, with no clinical trials having investigated the efficacy of shorter courses versus longer courses. For patients who are on a maintenance regimen that is not tacrolimus based, tacrolimus conversion may also be considered in the setting of rejection with an inadequate response to corticosteroids,[53] whereas for patients on a corticosteroid-free regimen, reinstitution of maintenance prednisone may be warranted.[54]

For patients who do not respond adequately to corticosteroids, T cell–depleting agents are required. In a meta-analysis of randomized trials comparing monoclonal (OKT3) versus polyclonal (antilymphocyte globulin, antithymocyte globulin) antibody therapy, no differences were noted in reversal of rejection, prevention of subsequent rejection, or prevention of graft loss, but OKT3 (no longer

manufactured) was three times more likely to induce reactions of fever, chills, and malaise.[55] A typical course of rATG for T cell–mediated rejection is 1.5 mg/kg for 4 to 14 days dictated by clinical response and absolute lymphocyte counts, again with no controlled study having compared one treatment regimen versus another.

Acute Antibody-Mediated Rejection

Treatment of acute humoral rejection is indicated when the triad of graft injury, C4d staining in peritubular capillaries on biopsy, and circulating donor-specific antibody is present, but should also be considered in high-risk circumstances (prior desensitization or known donor-specific antibody) even if all three criteria are not met. High-quality randomized trials investigating treatment options for acute humoral rejection are lacking,[56] and strategies are generally dictated by center experience. Traditionally, treatment has entailed removal of the pathogenic immunoglobulin(s) with plasma exchange and inhibition or suppression of antibody production with IVIG. In general, at least five plasma exchange treatments should be administered with 1 to 2 g/kg total dose IVIG. Because IVIG is removed by plasma exchange, a common strategy is to administer IVIG 100 to 200 mg/kg after each exchange. For refractory acute humoral rejection, rituximab may be considered despite targeting B cells at an earlier phase of maturation than the antibody-producing plasma cell line.[57] In contrast, the proteosome inhibitor bortezomib directly inhibits antibody-producing plasma cells and has been reported in single-center case series as a potential treatment for refractory antibody mediated rejection, usually in combination with other modalities such as plasma exchange and IVIG.[58] Eculizumab is a humanized monoclonal antibody that blocks terminal complement activation and has been shown to significantly reduce the risk of acute humoral rejection as well as subsequent transplant glomerulopathy in patients who have undergone positive crossmatch kidney transplant.[59] Finally, there are case reports of splenectomy for refractory acute humoral rejection.[60] These therapies are typically coupled with targeted T cell therapy such as high-dose corticosteroids and/or depleting antibody therapy, because histologic evidence of mixed T cell rejection is often present and helper T cell function may contribute to an enhanced B cell response. Agents used for treatment of acute humoral rejection are summarized in Table 104-2.

Chronic Rejection (T Cell and/or Antibody Mediated)

T cell– or antibody-mediated injury in a graft without features of acute tissue injury remains a therapeutic dilemma in kidney transplantation. No specific intervention has been proven to be effective in reversing the chronic tissue injury; however, consideration should be given to optimizing or enhancing the maintenance immunosuppression by transitioning to tacrolimus-MMF therapy or increasing the dose of these agents if CNI nephrotoxicity is not identified.[61] Any intervention should be weighed against the potential for risk of enhanced immunosuppression and the lack of any long-term data describing the impact of enhancing immunosuppression. This topic is discussed in greater detail in Chapter 107.

PROGNOSIS

Episodes of acute rejection may predispose to chronic graft dysfunction, with increased histologic findings of chronic rejection and/or interstitial fibrosis and tubular atrophy and clinical findings of reduced graft survival. The clinical response to antirejection therapy appears to be critical in this regard, because the change in renal function from 6 and 12 months after transplant is more predictive of long-term graft survival than the occurrence of prior episodes of acute rejection.[62] Two analyses (one examining the U.S. experience[63] and another examining the Australia–New Zealand experience[64]) have shed light on risk factors for graft loss after episodes of acute rejection. In general, acute T cell–mediated rejection that responds to therapy with return to near-baseline renal function does not portend worse graft survival. However, vascular rejection, late rejection (after 3 months), and rejection that does not respond to within 75% of baseline serum creatinine are associated with worse graft outcomes. Although acute rejection rates have fallen significantly over the past decade, graft survival rates have not improved in similar fashion; one explanation for this finding is that the rejection now identified tends to be less responsive to therapy, with fewer patients achieving near-baseline serum creatinine levels. The long-term prognosis after episodes of acute antibody-mediated rejection has not been fully defined in prospective analyses; however, from single-center and retrospective studies it appears that episodes of acute humoral rejection likely affect long-term graft survival. Similarly, the emergence of *de novo* HLA antibodies at any time after transplant has been shown to be associated with a 5% worse graft survival per year compared with patients who do not form anti-HLA antibodies.[65] For this reason, patients who have experienced episodes of acute rejection must be rigorously monitored with optimization of baseline maintenance immunosuppression. Remaining questions include the value of escalated immunosuppression such as longer-term scheduled antibody therapy, or additional IVIG treatment for those without adequate clinical response or with persistently elevated titers of HLA antibodies.

SUMMARY

Acute rejection has decreased in incidence over time but remains an important cause of graft dysfunction and progressive graft loss, particularly when antibody-mediated forms of injury are identified. Although many immunosuppressive regimens have been used to minimize both the incidence of rejection and the side effect profile of chronic immunosuppressive agents, the most effective maintenance immunosuppressive regimen for the prevention of rejection is a three-drug regimen consisting of tacrolimus, mycophenolate, and prednisone. Higher-risk patients benefit from induction therapy with lymphocyte depleting agents for the prevention of rejection. Alternative immunosuppressive strategies may be considered for side effects or toxicities related to immunosuppressive agents, which in clinical practice has led to a myriad of treatment combinations (see Table 104-4). Until there is an accurate means of determining an individual patient's degree of immune function, suppression, or graft-specific immunity, the clinician must determine the best treatment regimen based on potency (minimizing rejection) and tolerability.

CHAPTER 105

Medical Management of the Kidney Transplant Recipient: Infections, Malignant Neoplasms, and Gastrointestinal Disorders

Phuong-Thu Pham, Gabriel M. Danovitch, and Phuong-Chi T. Pham

Although patient and graft survival rates in recipients of solid organ transplantation have improved significantly, malignant neoplasms and infectious complications continue to adversely affect post-transplantation morbidity and mortality. Antimicrobial prophylaxis has reduced the incidence of previously common infections such as cytomegalovirus (CMV) or *Pneumocystis,* but new or resistant microbial pathogens have emerged as a consequence of prophylactic antimicrobials and nosocomial exposures. In addition, donor-derived infections or malignancy can arise as a result of delayed donor seroconversion after a recent acute infection, unidentified pathogens in an organ donor, occult neoplastic disease at the time of organ procurement, or malignant transformation of donor cells. This chapter discusses infections and post-transplantation–related malignant neoplasms in recipients of kidney transplant. Post-transplantation infectious- and drug-related gastrointestinal complications are also discussed.

INFECTIOUS DISEASES

Infection follows cardiovascular disease as the second most common cause of death with a functioning graft in kidney transplant recipients. Predisposing risk factors include immunosuppression, indwelling Foley or vascular catheters, surgical drains, drug-induced leukopenia, and metabolic derangement. Epidemiologic exposures (travel to regions with endemic pathogens), shifts in nosocomial flora associated with repeated antimicrobial exposures (antimicrobial resistance), and improvement in molecular diagnostic assays have also contributed to the emergence of novel infections and changes in the epidemiology of infections.[1]

Immunizations Before and After Transplantation

All kidney transplant candidates should receive immunization for hepatitis B, pneumococcus, and other standard immunizations appropriate for age. Up-to-date recommendations for routine adult immunizations are available through the Centers for Disease Control and Prevention website (www.cdc.gov/vaccines/schedules/downloads/adult/adult-schedule.pdf). Vaccinations should be administered at least 4 to 6 weeks before transplantation to achieve optimal immune response and to minimize the possibility of live vaccine–derived infection in the post-transplantation period. Household members, close contacts, and health care workers should also be fully immunized.

A minimum of 4 weeks should elapse between live virus vaccine administration and transplantation. Live virus or live organism vaccines should be avoided after transplantation. These include measles-mumps-rubella (MMR), live oral polio and smallpox (vaccinia) (which are also contraindicated for household contacts), varicella, yellow fever, adenovirus, live oral typhoid (Ty21a), bacillus Calmette-Guérin (BCG), and intranasal influenza vaccine. In addition, exposure to persons who have chickenpox or herpes zoster should be avoided until the lesions have crusted over and no new lesions are appearing. Immunizations using inactivated or killed microorganisms, components, and recombinant moieties are safe for transplant recipients. These include hepatitis A and hepatitis B, pneumococcal, *Haemophilus influenzae* type b, inactivated polio, diphtheria-pertussis-tetanus (DPT), and *Neisseria meningitidis* vaccines.

Infection with influenza A (H1N1) virus has emerged as an important cause of morbidity and mortality in the general and dialysis population. Infected patients on chronic dialysis treatment were found to have a 10-fold higher mortality rate compared with the general population. Recipients of solid organ transplants have similarly been reported to be at risk for more severe disease. Hence, unless contraindicated, influenza A (H1N1) vaccine should be considered in all prospective kidney transplant candidates.

Most centers restart vaccinations 3 to 6 months after transplantation. Vaccination before the first 3 to 6 months after transplantation may result in suboptimal response and protection because of heavy immunosuppression. Currently existing data show no conclusive evidence for a link between vaccination and allograft dysfunction.[2] For recommendations for prophylaxis or vaccination for transplant recipients who travel to countries where endemic infections such as malaria are present, please refer to reference 3. Recommended immunizations before and after transplantation are listed in Table 105-1.

Infectious Causes

Both the type and occurrence of infections in the immunocompromised transplant recipient follow a "timetable pattern" (Table 105-2).[1]

Donor-Derived Infections

Donor-derived infections have remained the focus of increased attention since the 2007 report of transmission of human immunodeficiency virus (HIV) and hepatitis C virus (HCV) from an initially antibody-negative donor to four transplant recipients. Other reported donor-transmitted blood-borne and kidney infections include viral (hepatitis B virus [HBV], CMV, and BK virus [BKV], among others), parasitic (malaria, *Babesia,* and *Balamuthia*), bacterial (from undiagnosed bacteremia or renal infections), and fungal (*Candida* species) infections. In recent years, allograft-transmitted infections including lymphocytic choriomeningitis virus, West Nile virus, amebic meningitis, and rabies have been added to the list of unusual viral infections. In addition, transmission of common organisms

including methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and azole-resistant *Candida* species occurs with increased frequency despite routine surgical prophylaxis because of the emergence of antimicrobial resistance in both hospital and community settings. Currently, most organ procurement organizations in the United States perform nucleic acid testing (NAT) in an effort to more precisely identify HIV and hepatitis infections during the window period. High vigilance for donor-derived infections must be maintained.

Recommended Immunizations Before and After Transplantation*

Vaccine	Before Transplantation	After Transplantation
Measles-mumps-rubella	X	—
Diphtheria-tetanus-pertussis	X	Diphtheria and tetanus[a]
Varicella	X	Contraindicated
Poliovirus	X	Inactivated polio vaccine[b]
Haemophilus influenzae type b	X	X
Influenza	X	X[c]
Pneumococcus	X	X[d]
Hepatitis B	X	X[e]
Hepatitis A	X	X[f]
Human papillomavirus (HPV)	X[g]	—
Neisseria meningitidis	X[h]	X[h]
Zostavax	X[i]	—

Table 105-1 Recommended immunizations before and after transplantation. All patients who are at least 1 month post-transplant should receive seasonal influenza vaccine.[7] [a]Booster every 10 years. [b]For travelers to endemic areas (i.e., some parts of Asia, Africa). [c]Annually. [d]Every 3-5 years. [e]Monitor titers. [f]For travelers to endemic areas. [g]Nonpregnant female transplant candidates ages 9-26. [h]Recommended for military members; travelers to high-risk areas; properdin-deficient or terminal complement component–deficient patients; patients with functional or anatomic asplenia; college freshmen living on campus (American Society of Transplantation Infectious Diseases Guidelines[3]). [i]Consult with transplant infectious disease specialist.

Month 1 After Transplantation

In the first month after transplantation, donor- and recipient-derived infections with common nosocomial bacterial microorganisms and *Candida* species predominate. Infections caused by multidrug-resistant bacteria are center specific. Infections caused by multidrug-resistant bacteria including gram-positive bacteria (MRSA, VRE), extended-spectrum β-lactamases (ESBLs), gram-negative bacilli, and multidrug-resistant nonfermentative gram-negative bacilli have emerged as important causes of morbidity and mortality in organ transplantation worldwide. Strict adherence to isolation measures and proper hand washing should not be overlooked.

Most bacterial infections during this period involve wounds, catheters, and drainage sites. Aspiration pneumonia and urinary tract infections (UTIs) are common. The U.S. Renal Data System database revealed a cumulative UTI incidence of 17% during the first 6 months after transplantation and 60% at 3 years for women and 47% for men. Infections specific to kidney transplant recipients include perinephric fluid collections caused by lymphoceles, wound hematomas, or urine leaks; indwelling urinary stents; and UTIs secondary to urinary tract abnormalities, such as ureteral stricture, vesicoureteral reflux, or neurogenic bladder. Most UTIs are caused by gram-negative bacteria (*Escherichia coli,* Enterobacteriaceae, and *Pseudomonas*) and gram-positive bacteria *(Enterococcus).* Preventive measures for UTIs include early urethral catheter removal and antibiotic prophylaxis. Trimethoprim-sulfamethoxazole or ciprofloxacin prophylaxis during the first 3 to 6 months after transplantation may reduce the risk of UTIs threefold[4] and essentially eliminates urosepsis unless anatomic or functional derangement of the urinary tract is present. Strict aseptic surgical techniques and perioperative use of first-generation cephalosporins reduce the incidence of wound infections. Although uncommon, donor or recipient pretransplant colonization with multidrug-resistant strains may represent an important risk factor for infection with multidrug resistant bacteria in the post-transplant period. Except for herpes simplex virus (HSV), viral infections are uncommon during this period.

Months 1 to 6

During months 1 to 6, opportunistic infections secondary to immunosuppression are most common. Viral infections such as CMV, HSV, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), HBV, and HCV may occur from exogenous infection or reactivation of latent disease as a result of the immunosuppressed state. Reactivation

Timetable of Infections

Month 1 After Transplant	Months 1-6	After 6 Months
Bacterial infections (sources and sites) Urinary tract Respiratory Catheters, drainage sites Wound Intra-abdominal infections* Bacteremia Center-dependent multidrug-resistant species, *Clostridium difficile* Recipient pre-Tx colonization with multidrug-resistant species or untreated infection **Viral:** HSV, other viral infections uncommon **Fungal:** *Candida,* azole-resistant *Candida* species (recipient pre-Tx colonization or donor derived) **Organisms transmitted with donor organ** (see text)	**Opportunistic or unconventional infections** **Viral:** CMV, HHV-6, HHV-7, HBV, HCV, EBV, VZV, influenza, RSV, adenovirus, BK infection **Fungal:** *Aspergillus* species, *Cryptococcus, Mucor* **Bacterial:** *Nocardia, Listeria, Mycobacterium* species, *Legionella,* tuberculosis **Parasitic:** *Pneumocystis jiroveci, Toxoplasma* and *Strongyloides* species, leishmaniasis, *Trypanosoma cruzi*	**Late opportunistic infections:** *Cryptococcus,* CMV retinitis or colitis, VZV, parvovirus B-19, BK virus, *Listeria,* tuberculosis **Persistent infections:** HBV, HCV **Associated with malignancy:** EBV, papillomavirus, HSV, HHV-8 **Community acquired** **Unusual sites** (e.g., paravertebral abscess)

Table 105-2 Timetable of infections. Geographically focused infections, such as malaria, leishmaniasis, trypanosomiasis, and strongyloidiasis, will need to be considered in certain patients. *Sources of infections specific to recipients of renal transplant include perinephric fluid collections (e.g., lymphoceles, wound hematomas, urine leaks), indwelling urinary stents, or anatomic or functional genitourinary tract abnormalities (e.g., ureteral stricture, vesicoureteric reflux, neurogenic bladder). *CMV,* Cytomegalovirus; *EBV,* Epstein-Barr virus; *HBV,* hepatitis B; *HCV,* hepatitis C; *HHV,* human herpes virus; *HSV,* herpes simplex virus; *pre-Tx:* Pre-transplant; *RSV,* respiratory syncytial virus; *VZV,* varicella-zoster virus. *(Modified from reference 59.)*

Suggested Prophylactic Therapy for Recipients of Kidney Transplants

Regimen	Comments
Trimethoprim-sulfamethoxazole (TMP-SMX)* (80/400 mg) one tablet daily × 6-12 mo	Its routine use reduces or eliminates the incidence of *Pneumocystis jiroveci, Listeria monocytogenes, Nocardia asteroides,* and *Toxoplasma gondii.* In renal transplant recipients, TMP-SMX × 6 mo reduces the incidence of UTIs threefold.
Dapsone† > Atovaquone > monthly aerosolized pentamidine‡	Replaces TMP-SMX for patients with sulfa allergies. Consider adding fluoroquinolone or another agent for antibacterial activity.
Nystatin 100,000 units/ml, 4 ml after meals and before bedtime *or* Fluconazole§ 200 mg one tablet daily × 2 months	For fungal prophylaxis. Close monitoring of cyclosporine or tacrolimus or mTOR inhibitor levels is required when starting and stopping antifungal agents.
Acyclovir, valganciclovir, ganciclovir	For CMV prophylaxis, see Box 105-1.

Table 105-3 Suggested prophylactic therapy for recipients of kidney transplants. *CMV,* Cytomegalovirus; *mTOR,* mammalian target of rapamycin; *UTI,* urinary tract infection. *The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggest UTI prophylactic therapy for at least 6 months after transplantation. For patients receiving sirolimus immunosuppression, we recommend 1 year of therapy for *Pneumocystis* pneumonia prophylaxis. †Check glucose-6-phosphate dehydrogenase deficiency before initiation of therapy. ‡In order of preference. §Fluconazole recommended for recipients of combined kidney-pancreas or combined kidney-liver transplants. Consider reinstituting prophylactic therapy × 3 months after acute rejection episodes requiring intensification of immunosuppression.

or *de novo* HCV infection remains an important cause of morbidity and mortality after transplantation because of the lack of effective antiviral drugs and the risk of precipitating acute allograft rejection associated with interferon therapy. Repeated courses of antibiotics and corticosteroid therapy increase the risk of fungal infections, whereas viral infections not only may result from immunosuppression but may further impair immunity and increase the risk for additional opportunistic infections. Opportunistic infections may occur with *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*), *Aspergillus* species, *Listeria monocytogenes, Nocardia* species, and *Toxoplasma gondii.* Trimethoprim-sulfamethoxazole prophylaxis (see Table 105-3 for trimethoprim-sulfamethoxazole allergy) eliminates or reduces the incidence of *Pneumocystis*, *L. monocytogenes* meningitis, *Nocardia* species infection, and *T. gondii.* Reactivation of latent infection such as *Mycobacterium tuberculosis, Trypanosoma cruzi, Leishmania* species, *Strongyloides stercoralis, Cryptococcus neoformans, Histoplasma capsulatum,* and *Coccidioides* and *Paracoccidioides* species may be observed. Community-acquired respiratory viruses remain a common hazard in these vulnerable immunocompromised patients during this time period. Clinically, patients may present with pneumonitis, viremia, or tissue-invasive disease such as hepatitis or carditis.[1] Over the past two decades, BK polyomavirus–associated clinical syndromes have emerged as important complications in kidney transplant recipients (discussed further under BK infection).

After 6 Months

After 6 months, the infection risk is largely a function of chronic maintenance immunosuppression, exposure to T cell–depleting agents, graft function, and epidemiologic exposures. In essence, patients can be arbitrarily divided into three categories in terms of infection risks.

The first category consists of the majority of transplant recipients (70% to 80%), who have satisfactory or good allograft function, relatively low doses of immunosuppressants, and no history of chronic viral infection. The risk of infection is similar to that of the general population, with community-acquired respiratory viruses constituting the major infective agents. Opportunistic infections are unusual unless environmental exposure has occurred.

The second group (approximately 10% of patients) consists of those with chronic viral infection that may include HBV, HCV, CMV, EBV, BKV, or papillomavirus. In the setting of immunosuppression, such viral infections may lead to the development of progressive liver disease or cirrhosis (HBV, HCV), BK nephropathy, post-transplant lymphoproliferative disease (EBV), or squamous cell carcinoma (papillomavirus). The use of alemtuzumab (a humanized monoclonal antibody directed against CD52 found on T and B cells) has been reported to be associated with increased risk of late invasive viral and fungal infections because of its effect on profound and prolonged pan–T cell depletion. New infections occurring in this time period often reflect new exposures (e.g., *L. monocytogenes* [dietary indiscretions], Lyme disease, and malaria [travelers to endemic areas]).[1]

The third group (approximately 10% of patients) consists of those who experience multiple episodes of rejection requiring repeated exposure to heavy immunosuppression. These patients are the most likely to develop chronic viral infections and superinfection with opportunistic infections. Causative opportunistic pathogens include *Pneumocystis, Listeria, Nocardia, Cryptococcus,* and geographically restricted mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, and paracoccidioidomycosis). We advocate lifelong antifungal prophylaxis in high-risk transplant recipients such as those with a history of past infection or those who live in endemic areas. Environmental exposure (primarily avoidance of pigeons and areas of active building construction) should be minimized.

MANAGEMENT AND PROPHYLACTIC THERAPY FOR SELECTED INFECTIONS

The following section discusses selected important infections and suggested approaches to their management. Suggested prophylactic therapy in kidney transplant recipients is shown in Table 105-3.

Cytomegalovirus Infection

Cytomegalovirus infection may cause primary infection in a seronegative recipient (donor seropositive, recipient seronegative), reactivation of endogenous latent virus (donor seropositive or seronegative, recipient seropositive) or superinfection with a new virus in a seropositive recipient (donor seropositive, recipient seropositive). Primary CMV infection is usually more severe than reactivated infection or superinfection.

Clinical Manifestations

Cytomegalovirus infection may be asymptomatic, presenting as a mononucleosis-like syndrome or influenza-like illness with fever and leukopenia or thrombocytopenia, or a severe systemic disease. Hepatitis, esophagitis, gastroenteritis with colonic ulceration, pneumonia, carditis, and even otitis may occur. In enterically drained pancreas transplantation, CMV has been reported to cause a bleeding ulcer from the duodenal segment. Although chorioretinitis (associated with retinal hemorrhage) is a common manifestation of CMV disease in acquired immunodeficiency syndrome (AIDS)

patients, it seldom occurs in solid organ transplant recipients. Nonetheless, any organ system may be affected by CMV. Clinical manifestations usually occur 1 to 4 months after transplantation except for chorioretinitis, which occurs later in the transplant course. Results of quantitative CMV assays of serum in patients with invasive colitis and gastritis or neurologic disease including chorioretinitis are often negative. Diagnosis in such patients may require invasive testing and biopsies.

Immunomodulating Effects of Cytomegalovirus Infection

Cytomegalovirus infection is associated with immune modulation and dysregulation of helper and suppressor T cells. CMV infection may be a risk factor for acute and chronic allograft rejection, secondary infection with opportunistic agents (such as *Pneumocystis, Candida,* and *Aspergillus*), and reactivation of human herpesvirus 6 (HHV-6) and HHV-7 and may favor development of post-transplant lymphoproliferative disease. CMV infection is also associated with acceleration of HCV infection and the development of new-onset diabetes after transplantation.[5]

Risk Factors for Cytomegalovirus Infection

Donor and recipient seropositive status and the use of blood products from CMV-seropositive donors are well-established risk factors for CMV infection. Other factors associated with an increased risk of CMV infection include the use of antilymphocyte antibodies, prolonged or repeated courses of antilymphocyte preparations, comorbid illnesses, concomitant HHV-6 and HHV-7 viral infections, neutropenia, lack of CMV-specific $CD4^+$ and $CD8^+$ T cells, and acute rejection episodes. Mycophenolate mofetil (MMF) has been reported to increase the risk of CMV viremia and disease in some studies, especially in patients receiving more than 3 g/day. Although the cause-effect relationship of allograft rejection and CMV infection remains conjectural, several studies suggest that one may increase the risk of the other, possibly because of the release of inflammatory cytokines. Prevention of CMV infection, for example, results in a lower incidence of graft rejection.[6]

Prevention

Prophylactic therapy begins in the immediate postoperative period. Preemptive therapy involves treatment of those who are found to seroconvert by quantitative laboratory assays of the blood, such as CMV DNA polymerase chain reaction (PCR) or pp65 antigenemia during surveillance studies. The former assay is highly specific and sensitive for the detection of CMV viremia. The latter is a semiquantitative fluorescent assay in which circulating neutrophils are stained for nonspecific uptake of CMV early antigen (pp65). Screening for CMV is best performed using NAT methods, although CMV antigenemia assays are still being used by some centers. Currently, CMV prophylactic therapy is recommended over initiation of preemptive treatment after detection of CMV viremia or antigenemia.[7]

Various prophylactic and preemptive protocols have been developed. Oral acyclovir provides effective CMV prophylaxis only in recipients of seronegative donor organs. Oral or intravenous ganciclovir or oral valganciclovir provides superior prophylactic or preemptive therapy against primary CMV infection or CMV reactivation. The 2-year results of the Improved Protection Against Cytomegalovirus in Transplant (IMPACT) study demonstrated that in high-risk CMV D+/R– recipients, once-daily oral valganciclovir prophylaxis for 200 days provided a significant reduction in the incidence of CMV disease compared with the 100-day once-daily prophylaxis. Extended prophylaxis to 200 days did not increase the rate of ganciclovir-resistant CMV disease.[8] Furthermore, a cost-effectiveness model also demonstrated that extended prophylaxis using valganciclovir was cost-effective in reducing the incidence of events associated with CMV disease over a 5- and 10-year period.[9]

Seronegative individuals who receive organs from latently infected seropositive donors are at greatest risk for primary infection and severe CMV disease. Delayed-onset (or late-onset) CMV disease developing soon after completion of antiviral prophylaxis occurs in 15% to 38% of high-risk CMV D+/R– solid organ transplant recipients who received 3-month CMV prophylaxis[10] and is associated with poor patient and graft survival. In high-risk kidney transplant patients, the IMPACT study showed that CMV disease developed in 36.8% versus 16.1% in the 100- versus 200-day valganciclovir prophylaxis groups, respectively, at 12 months after transplantation. Other suggested risk factors for delayed-onset CMV disease include allograft rejection, overimmunosuppression, and lack of CMV-specific immunity.[11] The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines suggest oral ganciclovir or valganciclovir in CMV D+/R– or D+/R+ for at least 3 months after transplantation and for 6 weeks after treatment with T cell–depleting antibodies. Suggested CMV prophylaxis protocol is shown in Box 105-1.

Treatment

The 2010 International Consensus guidelines recommend valganciclovir (900 mg orally every 12 hours, adjusted according to glomerular filtration rate [GFR]), or intravenous ganciclovir (5 mg/kg every 12 hours, adjusted according to GFR) for nonsevere CMV disease. In patients with severe or life-threatening disease and in those with

Suggested Cytomegalovirus (CMV) Prophylaxis Protocol

For CMV (–) recipients of a CMV (–) organ
- Acyclovir 400 mg daily (for herpes prophylaxis) × 3 months
- CMV DNA q2wk × 3 months

For CMV (–) recipients of a CMV (+) organ
- During antibody treatment: DHPG* 5 mg/kg IV qd
- After antibody treatment: valganciclovir 900 mg† PO qd × 6 months
- If no antibody treatment: valganciclovir 900 mg PO qd × 6 months
- CMV DNA q2wk × 3 months

For CMV (+) recipients of a CMV (–) organ
- During antibody treatment: DHPG 5 mg/kg IV qd
- After antibody treatment: valganciclovir 900 mg PO qd × 6 months
- If no antibody treatment: valganciclovir 900 mg daily × 3 months
- CMV DNA q2wk × 3 months

For CMV (+) recipients of a CMV (+) organ
- During antibody treatment: DHPG 5 mg/kg IV qd, then
- After antibody treatment: valganciclovir 900 mg PO qd × 6 months
- If no antibody treatment: valganciclovir 900 mg daily × 3 months
- CMV DNA q2wk × 3 months

Box 105-1 Suggested cytomegalovirus prophylaxis protocol. If CMV status is unknown, give intravenous DHPG until CMV status determined. *DHPG,* 9-(1,3-Dihydroxy-2-propoxymethyl) guanine. *Dose adjustment for renal function necessary. †Although low-dose valganciclovir 450 mg daily has been used successfully by some centers, there are insufficient data to support the routine use of low-dose valganciclovir. Such an approach may increase the risk of breakthrough disease and development of resistance in CMV (–) recipient of a CMV (+) organ.[12a]

impaired absorption or who are intolerant of oral medication, intravenous ganciclovir should be used. Antiviral drug dose reduction because of side effects should be done judiciously to avoid loss of efficacy. Reduction or withholding of mycophenolic acid products, azathioprine (AZA), or trimethoprim-sulfamethoxazole should be considered before valganciclovir or ganciclovir dose reduction. Severe leukopenia (absolute neutrophil count <500 to 1000/mm^3) can be treated with granulocyte colony-stimulating factor (G-CSF). Treatment should be continued until clearance of viremia as assessed by PCR or antigenemia, but not shorter than 2 weeks. Reduction of immunosuppression should be considered in severe disease, in slow responders or nonresponders, and in those with high viral loads or leukopenia. The use of CMV immunoglobulin in the treatment of CMV disease may be considered as adjunctive therapy in individuals with hypogammaglobulinemia, in nonresponders to standard therapy, or in those with severe forms of CMV disease such as pneumonitis.[12]

Laboratory monitoring for CMV should be performed weekly during treatment. Results of at least two CMV PCR assays performed 1 week apart should be negative before discontinuation of treatment. Secondary prophylaxis with 900 mg valganciclovir once daily for 1 to 3 months should be considered. Studies evaluating the clinical predictors of relapse after treatment of primary gastrointestinal CMV disease in solid organ transplant recipients showed that only extensive involvement of the gastrointestinal tract was significantly associated with CMV relapse, whereas seroconversion, viral load, treatment duration, maintenance therapy, and endoscopic evidence of resolution of gastrointestinal disease did not translate into a lower risk of CMV relapse.[11]

An emergence of ganciclovir-resistant CMV has been reported to be a result of a mutation in a viral kinase (UL97) that prevents the phosphorylation of ganciclovir to its active form. Cidofovir and foscarnet should be reserved for those with clinically suspected ganciclovir-resistant strains because of their associated nephrotoxicity and potential synergistic nephrotoxicity with calcineurin inhibitors (CNIs). Nonetheless, mutation in the *UL54* gene, which encodes for CMV DNA polymerase (a target for all currently available systemic anti-CMV drugs) could lead to cidofovir or foscarnet resistance or cross-resistance among ganciclovir, foscarnet, and cidofovir.[10]

Candida Infections

Candida infections are common in transplant recipients; *Candida albicans* and *Candida tropicalis* account for 90% of the infections. Risk factors include diabetes, high-dose corticosteroids, broad-spectrum antibacterial therapy, indwelling urinary tract device, and rarely, donor-derived candidiasis (estimated frequency 1:1000 in one study).[13] The latter is thought to be caused by contamination of the preservation fluid before or at the time of organ procurement, or contamination from a ruptured abdominal viscus. When *Candida* is visualized on stains or grown in preservation fluid or when organs are recovered from donors with bowel perforation, cultures from the blood, urine, and other clinically relevant sites should be obtained in the recipient and antifungal therapy initiated.[14] Fluconazole is considered the drug of choice for the prevention or treatment of donor-derived candidiasis.[14]

Superficial candidal infections involving the mouth or intertriginous areas can be treated with nystatin and topical clotrimazole, whereas candidal UTIs require systemic antifungal therapy (see Chapter 55). Whenever possible, foreign objects such as bladder catheter, surgical drains (such as percutaneous nephrostomy tube), and urinary stents should be removed. Management of asymptomatic candiduria in immunocompromised patients is discussed in Chapter 55. Systemic antifungal therapy is indicated in the presence of any blood culture positive for *Candida* species.

BK Virus Infection

BK virus is a ubiquitous human virus with a peak incidence of primary infection in children 2 to 5 years of age and a seroprevalence rate of greater than 60% to 90% among the adult population worldwide. After primary infection, BKV preferentially establishes latency within the genitourinary tract and frequently reactivates in the setting of immunosuppression. In kidney transplant recipients, BKV is associated with a range of clinical syndromes including asymptomatic viruria with or without viremia, ureteral stenosis and obstruction, interstitial nephritis, and BK allograft nephropathy (BKN). Most series have reported that 30% to 40% of renal transplant recipients develop BK viruria, 10% to 20% develop BK viremia, and 2% to 5% develop BKN. The highest prevalence of BK viruria and viremia occurs at 2 to 3 months, and 3 to 6 months, respectively. The risk for BK viremia increases when urine viral load is greater than 10^4 copies/ml, and BKN is unusual in the absence of BK viremia. However, PCR assays are not standardized, and the sensitivity and specificity of the assays may vary among centers.

BK is an important cause of allograft dysfunction and graft loss, and commonly presents with an asymptomatic rise in serum creatinine during the first post-transplantation year. However, BKN may occur as early as the first week and as late as 6 years after transplantation. Diagnosis is made by allograft biopsy that demonstrates BK viral inclusions in renal tubular cell nuclei and occasionally in glomerular parietal epithelium (Fig. 105-1). Interstitial mononuclear inflammation, often with many plasma cells, degenerative changes in tubules, and focal tubulitis, may mimic acute rejection (see Fig. 105-1). BKN often is associated with very focal and sharply demarcated areas of tubulointerstitial inflammation, corresponding to foci of viral infection. Additional diagnostic studies include immunohistochemistry, *in situ* hybridization, or electron microscopy. Approximately 50% of biopsies showing BKN have tubular basement membrane deposition of BK viral antigen containing immune complexes. BK infection and acute rejection may occur simultaneously, and distinguishing between BKN and acute rejection or the presence of both can be a diagnostic challenge. In the late stage of BKN, only a few characteristic intranuclear inclusions are seen and the histopathologic changes may be indistinguishable from those of chronic rejection or nonspecific interstitial fibrosis and scarring, although inflammation may be more marked in BKN. The histologic classification system for BKN based on the degree of active inflammation, acute tubular injury, and tubulointerstitial scarring may have prognostic significance. One single-center retrospective study showed that among individual histologic parameters, only a higher degree of interstitial inflammation was an independent predictor of BKN progression at 3-month follow-up.[15]

Treatment strategies for BK viremia with or without BK nephropathy vary among centers. However, immunologic containment of BKV replication is accepted as the mainstay of therapy. Suggested strategies for reduction in immunosuppression include reduction or discontinuation of antimetabolites (MMF or AZA), judicious reduction in CNI or corticosteroid therapy, or immunosuppressant class switching.

Registry analyses suggest that tacrolimus is associated with a higher risk of BK reactivation than cyclosporine A (CSA).[16] The DIRECT (*D*iabetes *I*ncidence After *R*enal Transplantation: Neoral *C*[2] Monitoring Versus *T*acrolimus) (in which *de novo* transplant recipients were randomized to receive either CSA or tacrolimus)

demonstrated a lower incidence of BK viremia in CSA-treated patients compared with their tacrolimus-treated counterparts at 1 year (5% vs. 12%, $P < .12$).[17] *In vitro* studies suggest that CSA may exert an antiviral effect on BKV via suppression of viral replication that is not observed with tacrolimus.[18] Nonetheless, not all studies demonstrated a lower incidence of BK viremia with CSA- compared with tacrolimus-treated patients.[19] The UNOS/OPTN (United Network for Organ Sharing/Organ Procurement and Transplantation Network) registry database demonstrated a lower 2-year cumulative incidence of BK treatment in primary kidney transplant recipients receiving mammalian target of rapamycin (mTOR) inhibitor therapy at hospital discharge when compared with patients on other regimens without an mTOR inhibitor (1.74% vs. 3.67%, respectively, $P < .001$).[16] mTOR inhibition may promote differentiation of antiviral memory CD8 T lymphocytes.[20] Nonetheless, BKV infection has been reported to occur under all combinations of immunosuppressive therapy.

In BKV-associated disease refractory to reduction in immunosuppressive therapy alone, antiviral agents such as cidofovir, leflunomide, intravenous immunoglobulin (IVIG), and fluoroquinolones have been used in small series of patients with variable success. However, systemic review of 40 studies showed no graft survival benefit of adding cidofovir or leflunomide to immunosuppressive reduction for the management of BKN.[21] Although experimental studies suggest that human IVIG preparations contain BKV-neutralizing antibodies, one single-center study failed to demonstrate an association between antibody response and viral clearance.[22] It is speculated that humoral response offers incomplete protection, because interferon-γ secretion from BKV-specific T cells may be necessary for resolution of BK viremia. Fluoroquinolones inhibit BK DNA topoisomerase and SV40 large tumor antigen (T antigen) helicase, and potentially may help prevent BK viremia after renal transplantation.[23] However, the routine recommendation of fluoroquinolone prophylactic therapy in the post-transplant period awaits results of randomized, placebo-controlled trials.

Despite treatment, 30% to more than 60% of patients with established BKN show progressive decline in renal function with graft loss. Early diagnosis and intervention may improve prognosis. Therefore, intensive monitoring of urine and serum for BK by PCR and judicious reduction of immunosuppressive therapy are warranted. Monitoring for plasma BK alone appears to be cost-effective because BKN is unusual in the absence of BK viremia.[24] A proactive, preemptive approach often leads to resolution of viruria and/or viremia and halts the progression of BK viremia to BK nephropathy. The KDOQI guidelines recommend reduction in immunosuppression when BKV plasma NAT is persistently greater than 10^4 copies/ml. However, in our opinion the presence of rising plasma BKV DNA copies on serial measurements warrants immunosuppression reduction irrespective of BKV copy levels because early intervention prevents progression to BKN. Patients with biopsy-proven BKN and concurrent acute rejection should be treated with antirejection treatment, with subsequent reduction in immunosuppression.[24]

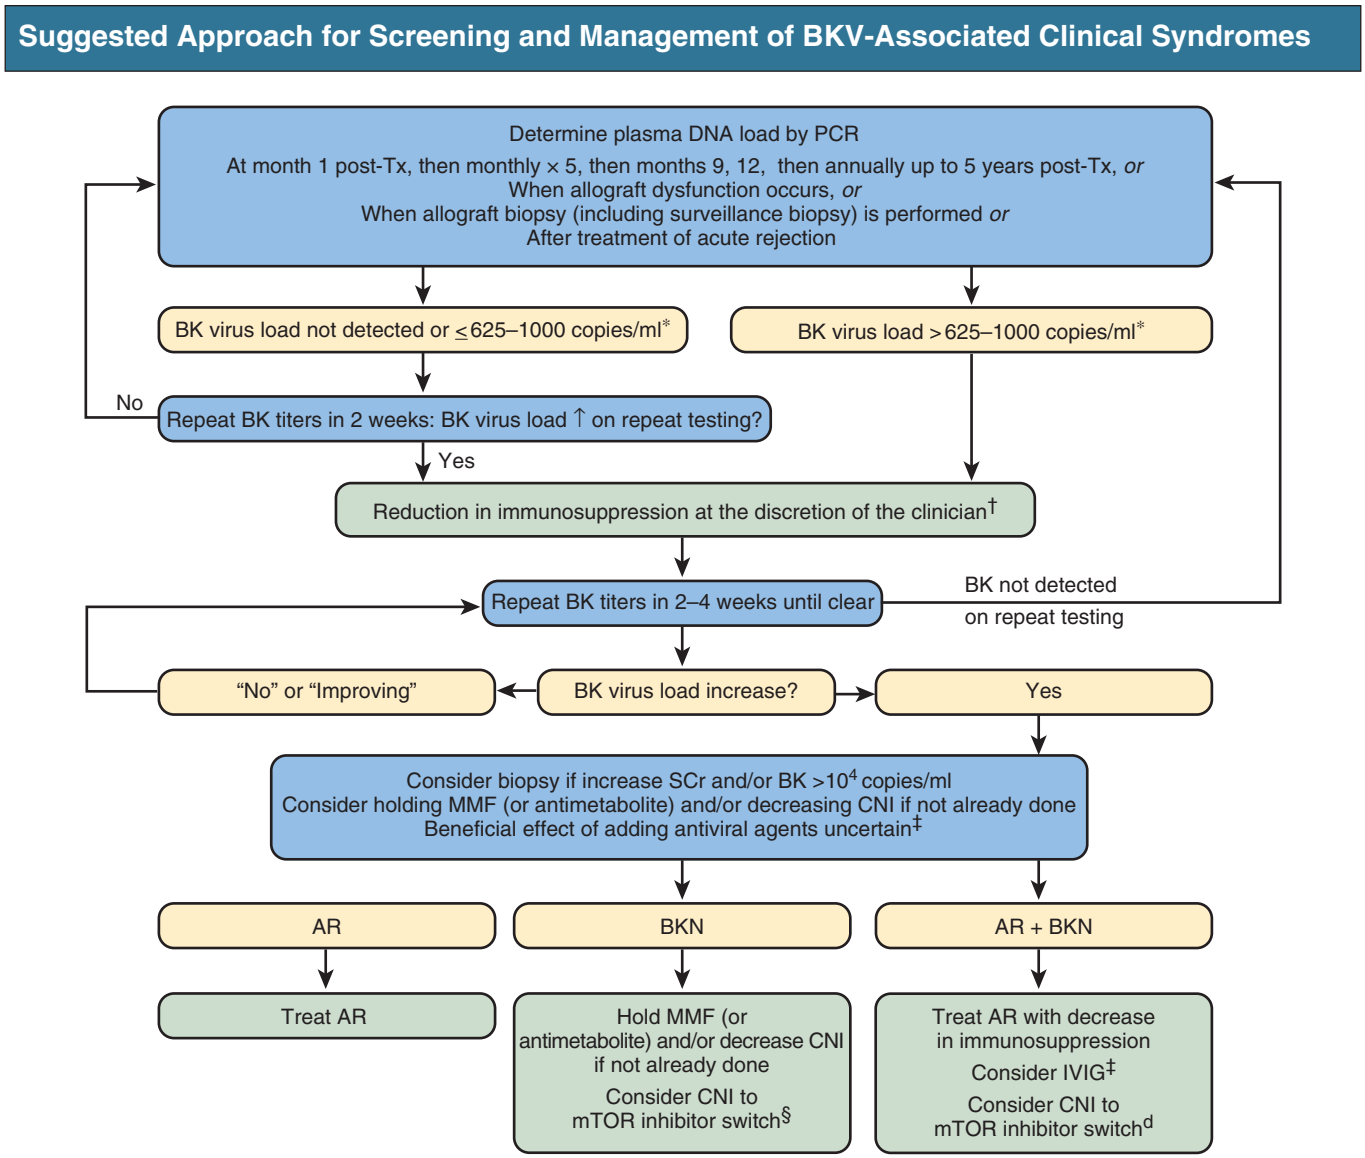

Figure 105-2 Suggested approach for screening and management of BK virus (BKV)–associated clinical syndromes. *No standardized PCR assays for BKV are currently available. Cutoff levels for viral detection should be based on PCR assays used at individual institutions. †Common practice: (1) decrease or hold MMF (or antimetabolite); (2) decrease MMF + CND by 25% to 50%; (3) decrease CNI. Less common practice: (1) decrease prednisone ± decrease CNI; (2) tacrolimus to CSA switch; (3) CNI to mTOR inhibitor switch ± decrease MMF (ongoing clinical trials).‡See text.§Evidence-based recommendations are lacking. May avoid long-term nephrotoxic effect of CNI therapy. Not recommended in patients with baseline significant proteinuria (arbitrarily defined as ≥500 mg/24 h). *AR,* Acute rejection; *BKN,* BK nephropathy; *CNI,* calcineurin inhibitor; *CSA,* cyclosporine A; *IVIG,* intravenous immunoglobulin; *MMF,* mycophenolate mofetil; *mTOR,* mammalian target of rapamycin; *PCR,* polymerase chain reaction; *post-Tx,* post-transplant; *SCr,* serum creatinine.

Anecdotal reports suggested that IVIG may be effective in treating corticosteroid-resistant rejection, and its use may be beneficial in patients with concomitant rejection and BKN or in those with histopathologic changes that are indistinguishable from those of rejection. Suggested guidelines for post-transplant screening and monitoring for polyomavirus replication are shown in Figure 105-2.[24] Patients with graft loss resulting from BKN can safely undergo retransplantation, but preferably after BK viral clearance. Active surveillance for BKV reactivation after transplantation is recommended.

Other Infections

Tuberculosis (TB) remains an important cause of morbidity and mortality in solid organ transplantation. Its incidence among renal transplant recipients is 20 to 70 times higher than that of the general population, whereas its prevalence reflects the prevalence of specific geographic areas (e.g., 13% in the Indian subcontinent including India and Pakistan; 2.0% in the Far East including China, Thailand, and Taiwan; and 0.07% to 1.7% in Western Europe and North America).[25] Although TB commonly results from inhalation of airborne bacilli, it more commonly emerges from the reactivation of dormant lesions in the setting of immunosuppressive therapy. Hence, all potential kidney transplant candidates should undergo a purified protein derivative (PPD) skin test (tuberculin skin test) before transplantation. In recent years, the use of interferon-γ release assays to diagnose latent TB is the preferred alternative to the PPD skin test (www.cdc.gov/mmwr/pdf/rr/rr5905.pdf). The interferon-γ release assay is useful in BCG-vaccinated patients to distinguish between BCG reaction versus TB reaction on PPD skin test. A positive skin

test or interferon-γ release assay result or a prior history of TB mandates further evaluation to rule out active disease. Isoniazid (INH) prophylaxis for a total of 9 months is recommended for those who have a positive skin test or interferon-γ release assay result. In patients with a known history of adequately treated TB infection, we advocate the use of INH prophylaxis for the first 9 months after transplantation and during intensification of immunosuppression. Others, however, have suggested that INH prophylaxis is not indicated for patients whose TB had been properly treated. Clinical, radiologic, or culture evidence of active TB infection is a contraindication to transplantation. INH prophylactic therapy should be considered in the following situations:

- Transplant candidates with a history of prior positive tuberculin skin test or interferon-γ release assay result
- Those with TB disease without adequate treatment
- Patients with evidence of old granulomatous disease on chest radiograph without treatment
- Those with known prolonged exposure to a person with active TB
- Kidney transplant recipients in endemic areas[25]
- Donor with positive tuberculin skin test or interferon-γ release assay result

A rare but important cause of infection in transplant patients, particularly those from endemic areas such as Southeast Asia, is *Strongyloides.* In the presence of immunosuppression, a "hyperinfection" syndrome may be observed with parasitic pneumonia and gastrointestinal involvement.

GASTROINTESTINAL DISEASE

Post-transplantation gastrointestinal complications are common. Only selected complications are discussed; a comprehensive review is provided in reference 26.

Drug-Related Gastrointestinal Complications

Mycophenolate mofetil causes gastrointestinal side effects including nausea, vomiting, dyspepsia, anorexia, flatulence, and diarrhea. Dose reduction, transient discontinuation of the drug, or dividing the dose for administration three or four times a day often ameliorates or resolves the symptoms. Switching to the enteric-coated formulation of MMF (enteric-coated mycophenolate sodium [EC-MPS]) may result in less gastrointestinal side effects. A randomized, multicenter, open-label study demonstrated that switching from MMF to EC-MPS may enable an increase in the maximum tolerated dose of mycophenolic acid and reduce gastrointestinal complications, hence enhancing patients' gastrointestinal health-related quality of life.[27] Conversion of MMF to EC-MPS should be considered in patients with gastrointestinal intolerance associated with MMF use.

Proton pump inhibitor (PPI) use can reduce the dissolution of MMF by increasing gastric pH.[28] In contrast to MMF, EC-MPS is not absorbed in the stomach and its bioavailability is not affected by PPIs. The latter formulation delays the release of mycophenolic acid. The clinical impact of such interactions (e.g., lower mycophenolic acid exposure and increased rejection risk in patients receiving MMF compared with EC-MPS–treated patients) remains to be studied.

Sirolimus may cause oral mucocutaneous lesions that can be confused with HSV or CMV infection but are culture negative. Drug-related oral ulcers usually resolve after discontinuation of the offending agent. Sirolimus, everolimus, tacrolimus, and cyclosporine may all cause diarrhea in some patients.

Infections

Post-transplantation infections of the gastrointestinal tract may have a viral, fungal, or bacterial cause. Viral infections are most commonly caused by CMV and HSV; *C. albicans* and *C. tropicalis* are common opportunistic fungal infections. Leukoplakia and post-transplant lymphoproliferative disorders (PTLDs) may develop in patients with EBV infection (PTLD is discussed in a later section). Commonly encountered bacterial pathogens include *Clostridium difficile* and *Helicobacter pylori.*

Cytomegalovirus Infection

Cytomegalovirus can affect any segment of the gastrointestinal tract. Patients may present with dysphagia, odynophagia, nausea, vomiting, gastroparesis, abdominal pain, diarrhea, or gastrointestinal bleeding. Leukopenia and elevated transaminases are common. Persistent or unexplained symptoms of nausea, vomiting, or diarrhea, particularly in the early post-transplantation period or during intensification of immunosuppression, warrant further investigation with upper and lower endoscopies and biopsies.

Herpes Simplex Virus Infection

Herpes simplex virus infection results primarily from reactivation of endogenous latent virus, causing clinical infection within the first 1 to 2 months after transplantation. Patients commonly present with oral mucocutaneous lesions or gingivostomatitis with or without odynophagia and dysphagia. HSV esophagitis has been noted to occur in patients receiving high-dose corticosteroids and antilymphocyte preparations for acute rejection. Limited oral mucocutaneous lesions are treated with oral acyclovir; extensive infections require intravenous acyclovir or ganciclovir. Rare cases of HSV hepatitis have been reported. The routine use of acyclovir prophylaxis in the early post-transplantation period is recommended (see Table 105-3).

Fungal Infections

Candida stomatitis and esophagitis are common during the first 6 months after transplantation and are increased in patients with leukopenia, severe immunosuppression, diabetes, or concomitant infections. Bleeding or perforation with formation of tracheoesophageal fistulas has been reported. The use of prophylactic oral nystatin "swish and swallow" during the first month after transplantation is recommended. In high-risk candidates, including liver or pancreas transplant recipients and those receiving antilymphocyte antibody therapy, fluconazole prophylactic therapy (3 to 6 months) is warranted.

Helicobacter Infection

Helicobacter pylori infection is associated with a wide range of gastrointestinal complications including chronic gastritis, duodenal and gastric ulcers, mucosa-associated lymphatic tissue (MALT) lymphoma, and gastric carcinoma, both in the general population and in recipients of solid organ transplants. Treatment includes a triple-drug regimen consisting of two antibiotics and an acid-suppressive agent such as an H_2-blocker or a PPI. The first-line *H. Pylori* regimen is shown in Table 105-4. In recipients of orthotopic heart transplant, triple-drug therapy resulted in a lower eradication rate compared with the general population, suggesting that immunosuppression may hinder the clearance of *H. pylori.* Unexplained dyspeptic or reflux symptoms should be investigated further with endoscopy and biopsy to exclude malignancy. *H. pylori* is now recognized as a risk factor for MALT lymphoma, which may occur in kidney, liver, and heart transplant recipients. In kidney transplant recipients infected with *H. pylori,* MALT lymphoma may be less aggressive than other

First-Line Treatment Regimens for *Helicobacter pylori* as Recommended by the American College of Gastroenterology	
Penicillin Allergies	**Regimen**
No	Standard-dose PPI twice daily (or omeprazole once daily) + clarithromycin 500 mg twice daily + amoxicillin 1000 mg twice daily for 10-14 days
Yes	Standard-dose PPI twice daily + clarithromycin* 500 mg twice daily + metronidazole 500 mg twice daily for 10-14 days
Yes	Bismuth subsalicylate 525 mg orally four times daily + metronidazole 250 mg orally four times daily + tetracycline 500 mg orally four times daily + ranitidine 150 mg orally twice daily (or standard-dose PPI once to twice daily) for 10-14 days

Table 105-4 First-line treatment regimens for *H. pylori* as recommended by the American College of Gastroenterology. *PPI,* Proton pump inhibitor. *Close monitoring of cyclosporine or tacrolimus or mTOR inhibitor levels is required when starting and stopping clarithromycin.

lymphomas, and the disorder may be cured by eradication of *H. pylori.*

Colon Disorders

Diverticulitis and colonic perforations may be life-threatening and difficult to diagnose after transplantation because symptoms may be masked by immunosuppressive therapy, particularly in the early postoperative period. Diverticulitis complicated by perforation, abscess formation, phlegmon, or fistula has been reported in 1% of kidney transplant recipients, and its incidence may be increased in patients with polycystic kidney disease (PKD).

Early post-transplantation colonic perforations are largely caused by high-dose corticosteroids, diverticulitis, CMV colitis, and intestinal ischemia; perforations occurring late or years after transplantation are commonly caused by diverticulosis or malignant disease. Abdominal symptoms may be absent because of the effects of immunosuppression and may be suggested only by the presence of tachypnea and tachycardia. Mortality after colonic perforations is high. Management includes prompt exteriorization of the perforated colon, broad-spectrum antimicrobial therapy, and minimization of immunosuppressive therapy. Although uncommon, the presence of abdominal pain and gastrointestinal bleeding with unexplained fevers or weight loss should raise the suspicion for gastrointestinal TB. The characteristic endoscopic findings include circular ulcers, small diverticula, and sessile polyps. The presence of caseating granulomas, acid-fast bacilli, or both confirms the diagnosis.

TRANSPLANT-ASSOCIATED MALIGNANT NEOPLASMS

Recipients of organ transplants are at increased risk for development of neoplasms compared with the general population. The intensity and duration of immunosuppression as well as the ability of these agents to promote replication of various oncogenic viruses are important risk factors. The associations between human papillomavirus (HPV) and cervical and vulvar carcinoma, EBV and PTLD, HBV and HCV and hepatocellular carcinoma, and HHV-8 and Kaposi sarcoma are well established. Table 105-5 provides a summary of the incidence of cancers related to infections in transplant recipients.[29]

Meta-Analysis Standardized Incidence Ratios for Cancers Related to Infections in Transplant Recipients	
Cancers	**Meta-analysis SIRs**
EBV-related cancers	
Hodgkin lymphoma	3.9 (2.4-6.3)
Non-Hodgkin lymphoma	8.1 (6.4-10.2)
HHV-8–related cancer	
Kaposi sarcoma	208.0 (114-369)
HBV- and HCV-related cancer	
Liver	2.1 (1.2-3.9)
HPV-related cancers	
Cervix (uterine)	2.1 (1.4-3.3)
Vulva and vagina	22.8 (15.8-32.7)
Penis	15.8 (5.8-34.4)
Anus	4.9 (1.4-17.3)
Oral cavity and pharynx	3.2 (2.4-4.4)
Possibly HPV-related cancers	
Non–melanocytic-related skin	28.6 (9.4-87.2)

Table 105-5 Meta-analysis standard incidence ratios (SIRs) for cancers related to infections in transplant recipients. *EBV,* Epstein-Barr virus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HHV,* human herpesvirus; *HPV,* human papillomavirus. *(Adapted from reference 29.)*

Skin cancers are the most common *de novo* post-transplant tumors in the adult transplant population and occur with increasing frequency with time (skin cancers are discussed in a later section). Among nonskin malignant neoplasms, PTLDs are the most common type of post-transplantation malignancy, followed by lung, prostate, and kidney malignancies.[30] The mean time to diagnosis of different neoplasms varies with the type of organ involved. Kaposi sarcoma, PTLD, testicular cancer, cancer of the small intestine, and thyroid cancer occur early after transplantation (defined as less than 800 days after transplantation). An Italian multicenter cohort study demonstrated that kidney transplant recipients are at increased risk of developing Kaposi sarcoma and nonmelanoma skin cancer, followed by non-Hodgkin lymphoma, cancer of the cervix uteri, and thyroid cancer, compared with an age- and sex-matched reference general population.[31] Common cancers in the general population, including cancers of the breast, colon, prostate, lung, bladder, stomach, and pancreas, were found to occur more frequently in kidney transplant recipients in some but not all studies.[30-32] The KDOQI guidelines suggest an individualized screening plan for each kidney transplant recipient, taking into account the patient's past medical and family history, tobacco use, and competing risk for death, and the performance of the screening methodology. In patients with compensated cirrhosis, annual hepatic ultrasound and measurement of alpha fetoprotein level is recommended. Screening for cervical, breast, prostate, and colon cancer should follow local guidelines for the general population. Standard cancer surveillance appropriate for age is shown in Table 105-6. In patients with a history of preexisting malignant neoplasms, close monitoring for recurrences in the post-transplantation period is mandatory. The highest recurrence rates have been observed with multiple myeloma (67%), nonmelanoma skin cancers (53%), bladder carcinomas (29%), sarcomas (29%), symptomatic renal cell carcinomas (27%), and breast carcinomas (23%).[33] In an analysis of the Israel Penn International Transplant Tumor Registry involving 90 patients with a history of pretransplant prostate adenocarcinoma (77 renal, 10 heart, and 3 liver transplant recipients), prostate cancer recurrences were shown to be related to the stage of disease at initial diagnosis. Tumor recurrence rates were 14%, 16%, and 33% for stage I, II, and III disease, respectively

Preventive Care Recommendations for Cancer Surveillance in Kidney Transplant Recipients

Screening For	Starting at Age	Preventive Care	Screening Frequency
Colorectal cancer	Average risk: 50 years	Colonoscopy or FOBT + flexible sigmoidoscopy*	Colonoscopy: every 10 years FOBT*: every year Flexible sigmoidoscopy†: every 5 years
		Colonoscopy or or or	Every 5 years if a parent or sibling had colorectal cancer at younger than 60 years At 10 years younger than the youngest family member with cancer Every 10 years if the relative was older than 60 years Consider referral to medical genetics if two or more first-degree relatives had colorectal cancer
Skin cancer	Monthly self-examination of skin, total-body skin examination every 6-12 months by qualified physicians and dermatologists‡		
Females			
Breast cancer	50-69† years	Breast examination and screening mammography	Every 1 or 2 years
	40-49 years Before age 30 years (if mother or sister had breast cancer)	Breast examination and screening mammography	Every 1 or 2 years (no evidence for or against screening for this age group)
Cervical cancer	Once sexually active	Pap smear and pelvic examination	Every year
Males			
Prostate cancer	50 years 40§ years	Digital rectal examination PSA testing	Every year Frequency for testing is not established

Table 105-6 Preventive care recommendations for cancer surveillance in kidney transplant recipients. *FOBT,* Fecal occult blood testing; *PSA,* prostate-specific antigen. *As recommended by the American Transplant Society and the European Best Practice Guidelines on renal Transplantation. †The U.S. Preventive Services Task Force (USPSTF) recommends against routine screening in adults ages 76 to 85. ‡The American College of Preventive Medicine recommends regular screening for high-risk individuals but none for low-risk individuals. §Recommended for African Americans, patients with a family history of prostate cancer, patients receiving chronic immunosuppression for organ transplantation. *(Based on the 2008 joint guideline from the American Cancer Society, the U.S. Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology[60] and reference 58.)*

(American Joint Committee on Cancer, TNM staging system). Hence, a longer waiting time may be necessary for more advanced disease.[34] Nonetheless, the usefulness of clinical staging in predicting recurrence of localized prostate cancer in the general population has recently been questioned by experts in the field. Guidance on tumor-free waiting periods in potential recipients before transplantation is given in Chapter 102 (Box 102-2).

Post-transplant Lymphoproliferative Disorder

Post-transplant lymphoproliferative disorder encompasses a wide spectrum of lymphoid proliferations ranging from reactive polyclonal lesions to frank malignant monoclonal lymphomas. The 2008 modified World Health Organization (WHO) classification of PTLD can be divided into four subtypes including (1) early lesions, (2) polymorphic PTLD, (3) monomorphic PTLD, and (4) classic Hodgkin lymphoma–type PTLD (Box 105-2). The majority of PTLDs are non-Hodgkin lymphoma of B cell origin, 80% to 90% of which are linked to EBV infection. In recent years an increased incidence of EBV-negative PTLD has been reported. PTLD commonly occurs in the first year after transplant, although the cumulative incidence increases with time after transplantation. In a retrospective analysis of registry data for 402 recipients of kidney transplants, PTLD occurred at a median of 18 months after transplantation. The UNOS/OPTN database similarly demonstrated that PTLD occurred at a median of 18.5 months after transplantation.

Very late PTLD occurring more than 10 years after transplantation has been reported to occur in older adult transplant recipients.[35]

World Health Organization (WHO) Classification of Post-transplant Lymphoproliferative Disorder (PTLD)

1. Early Lesions
Plasmacytic hyperplasia
Infectious mononucleosis–like lesion

2. Polymorphic PTLD

3. Monomorphic PTLD

B Cell Neoplasms
- Diffuse large B cell lymphoma
- Burkitt lymphoma
- Plasma cell myeloma
- Plasmacytoma-like lesion
- Other

T Cell Neoplasms
- Peripheral T cell lymphoma, NOS
- Hepatosplenic T cell lymphoma
- Other

4. Classical Hodgkin Lymphoma-type PTLD

Box 105-2 WHO classification of PTLD. *NOS,* Not otherwise specified.

Risk factors for PTLD can be classified into those associated with the type of organ transplant, recipient age, type and intensity of immunosuppression, infectious agents, and human leukocyte antigen (HLA) mismatch.

Risk Factors

Type of Organ Transplant The incidence of PTLD varies according to the type of the transplanted organ. It occurs in 1% to 2% of patients after kidney transplantation, 1% to 4% after liver transplantation, 2% to 3% after pancreas or simultaneous kidney-pancreas transplantation, 2% to 10% after heart, lung, and heart-lung transplantation, and up to 33% after small bowel and multivisceral transplantation. The high incidence of PTLD in bowel and multiorgan transplants has been attributed to the use of more intensive immunosuppression and the amount of donor-derived lymphoid tissue transferred at organ transplantation. This lymphoid tissue has been suggested to act as a reservoir for viruses such as EBV.[36]

Age Post-transplant lymphoproliferative disorder is the most common malignancy in children, whereas in adults it is the second most common malignancy after skin cancer. The higher incidence of PTLD in children compared with adults has been attributed to the pretransplant EBV-naive status of children and the well-described association between primary EBV infection and PTLD.

Type of Immunosuppression

Calcineurin Inhibitors Cyclosporine and tacrolimus may enhance the development of EBV-associated PTLD by directly promoting survival of EBV-infected B cells, presumably via the inhibition of EBV-transformed cells from apoptosis.[37] Tacrolimus has been reported to increase the risk of PTLD by twofold to fivefold compared with cyclosporine.[38]

mTOR Inhibitors Sirolimus has been shown to have a strong antiproliferative effect on PTLD-derived B cell lines.[39] Experimental studies suggest that mTOR inhibitors may be beneficial in reducing the incidence of PTLD in high-risk patients or as an alternative method of immunosuppression in patients with established PTLD.[40,41] However, a higher incidence of PTLD associated with the use of sirolimus-containing regimens compared with "no sirolimus" has also been described. The UNOS/OPTN database demonstrated that in EBV (–) recipients, mTOR inhibitor–tacrolimus combination therapy was associated with a 1.4-fold increased PTLD risk, compared with MMF-tacrolimus combination therapy).[42] Analysis of 719 patients with PTLD similarly demonstrated that *de novo* sirolimus was associated with a 1.2-fold increased risk of PTLD in EBV (–) kidney transplant recipients.[43] It is conceivable that studies evaluating the association of sirolimus and PTLD risk have yielded conflicting results because of differences in methodologies and in overall intensity of induction and maintenance immunosuppression among studies. Limited studies also suggest that high-dose mTOR inhibitor maintenance therapy may carry an increased PTLD risk.[44]

Antimetabolites The use of antimetabolites such as AZA and MMF has not been consistently associated with an increased risk of PTLD. A lower or no increased risk has been observed.[45]

Induction Agents Whereas induction therapy with muromonab-CD3 (OKT3) or antithymocyte globulin has been reported to increase PTLD risk, the use of interleukin (IL)–2 receptor inhibitors (daclizumab and basiliximab) or anti-CD52 antibody (alemtuzumab) induction has not been suggested to increase PTLD risk.[46] Analysis of the UNOS/OPTN database demonstrated that thymoglobulin was associated with significantly increased PTLD risk, whereas alemtuzumab, basiliximab, and daclizumab trended toward a protective effect ($P = .06$). In this study maintenance therapy with an mTOR inhibitor was unexpectedly found to be strongly associated with PTLD, in contrast to earlier reports suggesting its beneficial effect on PTLD because of its antiproliferative and antiangiogenic effects.[46] Although both alemtuzumab and thymoglobulin are T cell–depletional agents, the former has been shown to have a more pronounced B cell–depleting effect. It is speculated that depletional induction is not an independent risk factor for PTLD, but, rather, that maintenance drug selection and the balance between B and T cell depletion may be more relevant determinants of PTLD risk. Nonetheless, aggressive PTLD attributed to alemtuzumab induction has been reported.[47] Overall, the intensity of immunosuppression undoubtedly plays a role in the development of PTLD.

Belatacept Belatacept is a novel non–antigen-specific biologic agent that blocks T cell costimulatory signals, hence preventing T cell activation. Phase III clinical trials suggest that its use in transplant recipients with pretransplant EBV seronegativity is associated with an increased risk of PTLD.[48] Hence, belatacept use is contraindicated in transplant recipients with pretransplant EBV-seronegative or unknown EBV status.

Viral Infection

Epstein-Barr Virus During primary infection, EBV is incorporated into B lymphocytes and establishes lifelong latency. Immunocompetent hosts mount an antibody response and, more important, an EBV-specific cytotoxic T cell immune response. EBV-naive transplant recipients lack both virus-specific antibodies to neutralize the virions released by infected donor-derived B cells and EBV-specific T cells to control the outgrowth of subsequently infected recipient B cells.[36] Hence, an EBV (–) recipient with an EBV (+) donor is at greatest risk for developing PTLD.

Cytomegalovirus Antecedent history of CMV and post-transplant primary CMV infection have been suggested to be risk factors for PTLD. Studies in pediatric liver transplantation demonstrated that children who developed primary CMV infection had a fourfold to sixfold higher risk of developing PTLD.[49] It is speculated that the inflammatory cytokines released in the presence of a primary infection with CMV make the milieu more supportive of EBV proliferation.

Hepatitis C Virus Whereas HCV infection has been linked to increased risk of lymphoma among immunocompetent individuals, the association between HCV and PTLD after solid organ transplantation has not consistently been shown. A large transplant registry study failed to demonstrate the link between HCV and PTLD. However, the risk of PTLD was increased among 2.8% of patients with HCV who were reported not to have received immunosuppressive therapy. It is speculated that chronic antigenic stimulation of the intact immune system is necessary for the development of HCV-related lymphoproliferation.[50]

Miscellaneous Other suggested risk factors for PTLD include fewer HLA matches, pretransplant malignancy, and infections with HHV-8 and simian virus 40.

Clinical Manifestations

Post-transplant lymphoproliferative disorder may present with constitutional symptoms such as fevers, night sweats, malaise, and weight loss or with localized symptoms of the respiratory tract (infection or mass, including tonsillar or even gingival involvement), gastrointestinal tract (diarrhea, pain, perforation, bleeding, mass), or central nervous system (CNS) (headache, seizure, or confusion). Other clinical manifestations may include lymphadenopathy or symptoms related to allograft dysfunction or compression of surrounding structures. Extranodal involvement occurs in more than two third of patients.[51] In contrast to lymphomas in the general population, where CNS involvement is rare, the CNS is frequently involved in PTLD, occurring in up to 25% to 30% of patients, and can be the only site of disease. Early diagnosis requires a high index

of suspicion in the appropriate clinical setting and radiologic findings. Although computed tomography (CT) and magnetic resonance imaging (MRI) are the most commonly used imaging modalities in PTLD, 2-[fluorine-18]fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) scan is superior to conventional imaging methods for detecting extranodal localization. Tissue sampling is necessary for a definitive diagnosis and subcategorization of PTLD. Although measurement of EBV DNA has been suggested to be invaluable in the diagnosis and monitoring of PTLD,[52] clinical trials demonstrating the usefulness of monitoring EBV DNA in the diagnosis of PTLD in solid organ transplant recipients are lacking.

Treatment

Reduction or discontinuation of immunosuppressive therapy, particularly cyclosporine, tacrolimus, or MMF, is the first-line treatment; prednisone can be continued to prevent allograft rejection. Although sirolimus has antiproliferative effects, there is not yet sufficient evidence to recommend or refute its use as a therapy for PTLD. Suggested factors predictive of a poor response to reduction in immunosuppression alone include elevated lactate dehydrogenase (LDH), organ dysfunction at diagnosis, multiple organ involvement of PTLD, bulky disease, advanced stage, and older age.[44]

Rituximab, a chimeric monoclonal antibody with murine variable regions targeting the CD20 antigen and human IgG1-κ constant regions, has antitumor activity against CD20-expressing B cell lymphomas. In patients who fail to respond to manipulation of immunosuppression alone, rituximab has been used with variable success. Suggested favorable predictive factors for response include EBV-positive PTLD, a shorter interval from transplantation to diagnosis of PTLD, a smaller number of involved sites, and a normal LDH level. Chemotherapy is often used in patients refractory to reduction in immunosuppression and rituximab, in those with aggressive disease at presentation, or in those with lesions not amenable to surgery. The treatment regimens are similar to those used to treat non-Hodgkin lymphoma. These have included CHOP (cyclophosphamide, adriamycin, vincristine, and prednisone), VAPEC-B (adriamycin, etoposide, cyclophosphamide, methotrexate, bleomycin, and vincristine), and ProMACE-CytaBOM. CHOP-based chemotherapy with or without rituximab is the most widely used regimen.[51] Adverse effects of chemotherapy include high mortality rates from sepsis and treatment-related toxicities. Surgical resection with or without adjunctive local radiation has been suggested for localized disease. Local radiation has been advocated as the treatment of choice for PTLD involving the CNS.

Acyclovir and ganciclovir are of unproven benefit because their activity is dependent on intracellular phosphorylation by virally encoded thymidine kinase. EBV-driven lymphomas do not express thymidine kinase. An emerging treatment strategy involves the addition of arginine butyrate, an amino acid derivative that induces EBV thymidine kinase transcription. Experimental studies have shown that arginine butyrate renders latently infective EBV-immortalized B cells more susceptible to ganciclovir.[44] Clinical trials evaluating the safety and efficacy of arginine butyrate in combination with ganciclovir in EBV-associated PTLD or other EBV-associated malignancies are currently under way.

Poor prognostic factors include multiple- versus single-site involvement, tumor monoclonality, advanced age, CD-20–negative large cell lymphomas, recipient EBV-negative serostatus, and the use of antilymphocyte globulin or antithymocyte globulin, or OKT3. Other poor prognostic factors include WHO performance status score of 3 or 4 (a score of 3 is defined as confined to bed or a chair for more than 50% of waking hours, and a score of 4 as completely disabled), late onset of disease (defined as onset more than 1 year after transplant), elevated LDH, severe organ dysfunction, and CNS disease.[50,51] In recipients of kidney transplant with PTLD restricted to the allograft alone, transplant nephrectomy may improve survival.

Skin Cancers

Skin cancers are the most common *de novo* post-transplant tumors in the adult transplant population and may occur 20 to 30 years earlier in immunosuppressed patients compared with the general population. Whereas basal cell carcinoma is the most common type of skin cancer in the general population, squamous cell carcinoma is approximately twice as common as basal cell carcinoma. However, multiple cancerous lesions of different types may be observed (i.e., concomitant appearance of squamous cell and basal cell carcinoma). The incidence of skin cancers is 20 times higher in sun-exposed areas and 7 times higher in non–sun-exposed areas. Sirolimus may delay the onset or reduce the incidence of post-transplant skin and nonskin malignant neoplasms (discussed under management of post-transplantation malignancies).

Risk factors for skin cancers in immunosuppressed post-transplant recipients include light skin color, total sun burden and recreational sun exposure (ultraviolet light exposure), genetic factors, history or present use of AZA,[53] and duration of follow-up after transplantation. In addition, immunosuppression in combination with enhanced sunlight exposure may induce malignant changes in papilloma-induced warts.

Management of Immunosuppressive Therapy in Post-transplantation Malignant Neoplasms

There is no consensus on the management of immunosuppressive therapy in patients with post-transplantation malignant neoplasms. In principle, immunosuppression dose reduction improves immune surveillance against malignant cells. Nonetheless, this approach is not without its attendant risk of graft rejection and graft loss. However, there are no systematic studies to demonstrate whether immunosuppression reduction or withdrawal might alter the natural history of established post-transplantation malignant neoplasms. In our opinion, a switch from CNI to sirolimus or CNI minimization in conjunction with sirolimus may be a viable therapeutic option (the antitumoral effect of sirolimus is discussed later). In patients with metastatic cancer, manipulation of immunosuppression is probably futile, and the risk of rejection and graft loss necessitating a return to dialysis is likely to outweigh the benefit.

Studies suggest that immunosuppressive agents have different effects on cancer risk after transplantation. The carcinogenic effects of OKT3, antithymocyte globulin, cyclosporine, tacrolimus, and AZA have been well documented. In contrast to AZA, MMF has been shown to have an antiproliferative effect and has been suggested to be protective of post-transplantation malignant neoplasms.[54] Analysis of more than 17,000 adult patients with pre-existing diabetes indicated a significantly higher incidence of malignancy in AZA-treated than in MMF-treated patients (3.7% vs. 2.2%,). However, whether MMF is protective of post-transplant malignancies remains unclear. Further studies are needed. In clinical practice, MMF is generally discontinued in the presence of malignancies because of the theoretical risk of net protumor effect of overimmunosuppression.

Both preclinical and clinical studies have demonstrated that sirolimus and everolimus have antiproliferative and antitumoral effects. The 5-year malignancy data of the Rapamune Maintenance Regimen

trial demonstrated a lower incidence of both skin and nonskin cancers at 5 years after transplantation in recipients receiving sirolimus with CSA withdrawal at month 3 compared with those receiving sirolimus-CSA combination therapy.[55] Recent meta-analysis of five randomized controlled trials consisting of more than 1400 kidney transplant recipients similarly demonstrated that sirolimus-based immunosuppression significantly decreased the risk of both squamous cell carcinoma and basal cell carcinoma.[56] In a multicenter trial of secondary prevention involving kidney transplant recipients with at least one previous cutaneous squamous cell carcinoma, conversion from CNI to sirolimus was associated with a lower risk of subsequent skin cancers. The study also demonstrated that the earlier the conversion after an initial diagnosis of cutaneous squamous cell carcinoma, the greater efficacy.[57] It has been suggested that the protective effect of sirolimus against skin cancer is a result of its inhibition of several ultraviolet-induced mechanisms involved in skin carcinogenesis. Sirolimus therapy has also been reported to result in successful clinical and histologic remission of Kaposi sarcoma in kidney transplant recipients.[58] Although sirolimus appears to provide satisfactory outcomes in certain cancers after transplantation, its use in the management of malignancies after solid organ transplantation remains to be defined and should be tailored to each individual patient. Nonetheless, sirolimus has increasingly been used in the secondary prevention of skin cancer. It is our current practice to start patients with newly diagnosed skin cancer (or those with a history of skin cancer) on sirolimus or everolimus in conjunction with reduction or discontinuation of other immunosuppressants.

CHAPTER 106

Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Phuong-Thu Pham, Son Pham, Phuong-Anh Pham, and Gabriel M. Danovitch

The medical management of transplant-related complications is discussed in this chapter; post-transplant infections, gastrointestinal problems, and malignant neoplasms are discussed in Chapter 105.

CARDIOVASCULAR DISEASE

Cardiovascular (CV) disease is the most frequent cause of death with a functioning graft. In a large multicenter, international study consisting of more than 23,000 kidney transplant recipients, the cumulative incidences of coronary heart disease (CHD) at 1, 3, and 5 years after transplant were 3.1%, 5.2%, and 7.6%, respectively. Of nearly 700 CHD events that occurred in the first post-transplant year, 49% were nonfatal acute myocardial infarction (AMI) and 13% fatal AMI or sudden death.[1] Renal function, estimated glomerular filtrate rate (eGFR), and preexisting CV disease were found to be the most important risk factors for a CV event. Recently, an analysis based on the Assessment of Lescol in Renal Transplantation (ALERT) trial suggested that major CV events could be predicted with a seven-variable model including age, previous CHD, diabetes, low-density lipoprotein (LDL), creatinine, number of transplants, and smoking.[1a] Although kidney transplantation ameliorates some CV risks by restoring renal function, it introduces new CV risks, including impaired glucose tolerance or diabetes mellitus, hypertension, and dyslipidemia, which are derived in part from immunosuppressive medications. Kidney transplant recipients have both conventional and unconventional CV risk factors (Table 106-1).[2]

Conventional Cardiovascular Disease Risk Factors

Post-transplantation Hypertension

Hypertension is a risk factor for both CV disease and kidney graft failure, with a graded risk for graft failure with increasing levels of systolic and diastolic blood pressure.[3] Whether aggressive lowering of blood pressure retards the progression of graft failure beyond that of blood pressure control alone remains to be studied. Hypertension is common after transplantation and is present in 50% to 90% of kidney transplant recipients. Systolic blood pressure is highest immediately after transplantation and declines during the first year. In a Collaborative Transplant Study (CTS) registry, only 8% of transplant recipients had a systolic blood pressure below 120 mm Hg at 1 year; 33% had a blood pressure in the prehypertension range; 39% had stage 1 hypertension; and 20% had stage 2 hypertension despite antihypertensive therapy.[3] Risk factors for post-transplant hypertension include preexisting hypertension, cyclosporine (and to a lesser degree tacrolimus), corticosteroids, poor quality of donor organ, delayed graft function, chronic allograft injury, high body mass index (BMI) or excess weight gain, acute rejection episodes, recurrent or *de novo* glomerulonephritis (GN), and transplant renal artery stenosis. Sodium intake after transplantation may also be contributory in salt-sensitive hypertensive patients. In rare patients, excess renin output from the native kidneys may contribute to post-transplantation hypertension. In kidney transplant recipients with severe hypertension refractory to medical therapy, bilateral native nephrectomy has been reported to ameliorate blood pressure control.[4] Recently, renal artery nerve denervation has been reported to have benefit in nontransplant patients with resistant hypertension (see Chapter 38).[5] Whether native kidney sympathetic denervation procedures improve blood pressure control in kidney transplant recipients with refractory hypertension remains to be studied.

Management of post-transplantation hypertension should include identification and treatment of the underlying cause, lifestyle modifications (see Chapter 35), and treatment of associated CV risk factors. The initial target blood pressure goal is below 130/80 mm Hg, and in patients with proteinuria, below 125/75 mm Hg. Although JNC 8 blood pressure targets for diabetics and patients with chronic kidney disease are set at higher levels than those of JNC 7, whether patients with post-transplant hypertension benefit from higher blood pressure goals remains to be studied. Although there is a lack of controlled clinical trials related to selection of antihypertensive agent, we recommend β-blockers in the perioperative setting because they have been shown to reduce CHD events in high-risk candidates. In the early post-transplantation period, nondihydropyridine calcium channel blockers (CCBs) and diuretics are frequently used, the former for their beneficial effect on intraglomerular hemodynamics and the latter to eliminate salt and water in patients who are volume expanded postoperatively. Although one retrospective cohort study reported an unexpected association between the use of dihydropyridine CCBs and an increased risk for CHD,[6] results of another trial showed no significant association between any CV medication use (β-blockers, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], diuretics, CCBs, antiplatelet agents, and/or statins) and increased major cardiac event risks at 12 months.[7] Studies evaluating the effect of CCBs on renal function have similarly yielded mixed and even contradictory results. In proteinuric chronic kidney disease (CKD) patients, dihydropyridine CCB use was shown to be associated with increased risk of renal disease progression and death except when used in conjunction with angiotensin II blockade therapy. However, results of a meta-analysis of randomized controlled trials demonstrated that CCB improved allograft function and reduced graft loss.[8] The

Cardiovascular Risk Factors in Transplant Recipients			
Traditional		Nontraditional	
Modifiable	**Nonmodifiable**	**Modifiable (± Potentially Modifiable)**	**Nonmodifiable**
Hypertension Dyslipidemia Obesity Smoking	Family history Pre-Tx diabetes Male gender Age White race Cardiac troponin T History of pretransplant and post-transplant cerebrovascular disease	Anemia New-onset diabetes after transplantation Proteinuria Inflammatory cytokines ↑ C-reactive protein CMV infection* Hyperuricemia Delayed graft function† Impaired graft function‡ Left ventricular hypertrophy§ CD4 lymphopenia‖ Post-transplant lymphoproliferative disorder† Low albumin Hyperhomocysteinemia Recipient history of cancer† Duration of pretransplant dialysis†¶	Prior acute rejection Preexisting coronary artery calcification Deceased versus living donor Pre-Tx splenectomy

Potential Advantages and Disadvantages of Different Classes of Antihypertensive Agents*		
Classes of Drugs	**Advantages**	**Disadvantages**
β-Blockers	Perioperative use: ↓ coronary heart disease events	↑ Risk of bradycardia when used with nondihydropyridine calcium channel blocker Blunting of hypoglycemic awareness
Calcium channel blockers	↓ CNI-induced renal vasconstriction† ↑ CNI level (may permit CNI dose reduction by up to 40%)‡	Monotherapy with dihydropyridine calcium channel blocker should be used with caution§
Diuretics	Beneficial in patients who are volume expanded	Hyperuricemia, gout
ACE inhibitors, ARBs	↓ Proteinuria Potential renal protective and cardioprotective effects Beneficial in patients with post-transplantation erythrocytosis	Potential worsening of anemia
Aldosterone receptor blockers	May improve outcomes in heart failure	Severe hyperkalemia when used in combination with ACE inhibitor or ARB in patients with poor kidney function
α_2-Blockers	Benign prostatic hypertrophy Neurogenic bladder	
Direct vasodilators		Tachycardia
Central α-agonist		Depression

Table 106-2 Potential advantages and disadvantages of different classes of antihypertensive agents. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNI,* calcineurin inhibitor. *In general, there is no absolute contraindication to the use of any antihypertensive agent in renal transplant recipients. †Both dihydropyridine and nondihydropyridine CCBs. ‡Nondihydropyridine CCBs. §See text.

study findings suggest that treating 100 patients with average risk of graft loss over the first year (approximately 10%) with CCBs, compared with no treatment, would prevent three patients from losing their grafts, irrespective of the presence or absence of hypertension. However, CV disease events and mortality were not reported. Based on currently existing literature, there appears to be no contraindication to the use of CCs in the transplant setting, although monotherapy with dihydropyridine CCBs should be used with caution (see also Chapter 80).

Angiotensin-converting enzyme inhibitors and ARBs block calcineurin inhibitor (CNI) toxicity in experimental models and are protective in patients with CKD. However, they can cause acute changes in renal function as well as hyperkalemia and hence are usually not started until allograft function is stable. A meta-analysis of 21 randomized controlled trials demonstrated that ACE inhibitors and ARBs reduced proteinuria in transplant recipients, but they also lowered hematocrit by 3.5% and glomerular filtration rate (GFR) by 6 ml/min; there were insufficient data to determine the effect of ACE inhibitor or ARB use on patient or graft survival.[9] Serum potassium and creatinine concentrations must be closely monitored; if serum creatinine rises more than 30% above baseline, then transplant renal artery stenosis should be considered.

Because of the lack of conclusive evidence that one class of antihypertensive agent is superior to another in the transplant setting, treatment should be individualized. Potential advantages and disadvantages of different classes of antihypertensive agents in kidney transplant recipients are shown in Table 106-2.

Post-transplantation Dyslipidemia

Dyslipidemia is common after transplantation, in part because of the hyperlipemic effect of corticosteroids, cyclosporine, tacrolimus, sirolimus, and everolimus. Sirolimus and everolimus are associated with

the worst lipid profiles, followed by cyclosporine, and to a lesser extent tacrolimus. One single-center study demonstrated that the mean values of total cholesterol, LDL cholesterol, and triglycerides (TGs) and the incidence of CHD were higher among patients receiving mammalian target of rapamycin (mTOR) inhibitors compared with their CNI-treated counterparts (control group). However, the risk of CV events was not significantly higher among patients receiving mTOR inhibitors compared with controls at 4-year follow-up.[10] It is hypothesized that the antiproliferative effects of mTOR inhibitors may offset the adverse effects of hyperlipidemia. The dyslipidemic effect of mTOR inhibitors on the risk for CV disease events after kidney transplantation remains unclear; however, mTOR inhibitor–induced dyslipidemia should be treated aggressively. Other potential etiologic factors for post-transplant dyslipidemia include age, diet, rapid weight gain, hyperinsulinemia, preexisting hypercholesterolemia, allograft dysfunction, proteinuria, genetic predisposition, and the use of β-blockers and diuretics.

Although hyperlipidemia often improves within the first 6 months after transplantation as the doses of immunosuppressive agents are reduced, total and LDL cholesterol goals as defined by the National Cholesterol Education Program (NCEP) guidelines (www.nhlbi.nih.gov/about/ncep/index.htm) are usually not achieved. Hence, management of hyperlipidemia is usually required, and includes lifestyle changes (diet and exercise) and statins. In addition to their lipid-lowering effect, statins may offer protection against CV disease via their antiproliferative and anti-inflammatory properties and ability to reduce circulating endothelin-1, C-reactive protein levels, systolic and diastolic blood pressure, and pulse pressure.

The clinical benefits of statins in the general population have been demonstrated in several large randomized controlled trials. To date, there has been only one single prospective randomized trial in transplant recipients comparing statins (fluvastatin) with placebo—the ALERT study. The ALERT study showed that treatment of kidney transplant recipients with fluvastatin over a 5- to 6-year period significantly and safely reduced LDL cholesterol levels. The incidence of major adverse cardiac events was also shown to be reduced, albeit not statistically significantly. However, further analysis demonstrated a beneficial effect of early initiation of fluvastatin on outcome—the earlier the initiation of therapy, the greater the reduction in cardiac events. Patients who received statin therapy within the first 4 year after transplantation had a risk reduction of 64% compared with 19% for those who received therapy after 10 years. No statin effect on graft loss or doubling of serum creatinine was observed.[11-12] Despite the well-established efficacy and safety of the use of statins in transplant recipients, clinicians should be aware that the use of statins with CNIs, particularly cyclosporine, often results in a several-fold increase in statin blood level and an increased risk for myopathy and rhabdomyolysis.[13] Compared with other statins, simvastatin appears to be particularly prone to drug-drug interactions because of its extensive metabolism by CYP3A4.

Ezetimibe and statin combination therapy can significantly improve cholesterol control because of their complementary mechanisms of action. Ezetimibe blocks intestinal absorption of dietary cholesterol, whereas statin inhibits hepatic cholesterol synthesis. Ezetimibe used alone or as adjunctive therapy with statin appears safe and effective in the treatment of dyslipidemia in kidney transplant patients who are refractory to statin therapy. In a single-center study consisting of 67 patients with post-transplantation hyperlipidemia resistant to statins, treatment with ezetimibe alone or with ezetimibe and statin significantly reduced total cholesterol and LDL cholesterol by 25% and 34%, respectively, during the first month of treatment.[14] In another study of 56 kidney transplant recipients, the addition of ezetimibe to statin therapy slowed the decline in renal function compared with controls.[15] Whether ezetimibe-statin combination therapy is superior to statin-alone therapy in CV disease risk factor reduction remains to be elucidated.

Severe hypertriglyceridemia (TG level >500 mg/dl or 5.65 mmol/l) may occur with the use of sirolimus and everolimus. Management includes dose reduction, addition of a fibric acid derivative or nicotinic acid, and, in refractory cases, switching of sirolimus or everolimus to mycophenolate mofetil (MMF) or tacrolimus. The National Kidney Foundation expert panel recommends gemfibrozil as the fibrate of choice. However, fibrates should be avoided in those with CKD stage 5. Of the major fibric acid medications (bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil), the first three can increase serum creatinine in cyclosporine-treated patients. Although all fibrates in combinations with statins have been associated with creatinine kinase elevations with or without overt rhabdomyolysis and myopathy, gemfibrozil may have a greater risk for the development of myopathy compared with bezafibrate or fenofibrate.[13]

Niacin monotherapy has not been reported to cause myopathy, but its combined use with lovastatin, pravastatin, or simvastatin may be associated with rhabdomyolysis. Bile acid sequestrants must be used with caution because of their potential interference with the absorption of CNIs and mycophenolic acid derivatives. Coadministration of bile acid sequestrants and mycophenolic acid products is not recommended. It should also be noted that studies in the general population suggest that bile acid sequestrants may increase TG levels. A more complete list of drug-drug interaction of statins with other lipid-lowering agents is provided in reference 13.

Statins should be the first-line therapy for the treatment of non–high-density lipoprotein (non-HDL) cholesterol because of their well-established safety and efficacy in preventing CV disease in randomized trials in the general population. Fibrates should be considered in those intolerant to statins despite dose reduction or despite switching to another statin. There are currently no data to suggest that adding fibrates to statin therapy is superior to adding nicotinic acid to statin therapy (or vice versa) in the treatment of post-transplant hypertriglyceridemia. Hence the choice of one agent over the other should be based on adverse effects and potential drug-drug interactions.

For patients with fasting TG levels above 1000 mg/dl (11.3 mmol/l), the Adult Treatment Panel (ATP) III recommends a very-low-fat diet (<15% total calories), medium-chain TGs, and fish oils to replace some long-chain TGs.

Suggested guidelines for pharmacologic treatment of dyslipidemia are summarized in Figure 106-1.

New-Onset Diabetes After Transplantation

New-onset diabetes mellitus after transplantation (NODAT) occurs in 4% to 25% of kidney transplant recipients. Variations in incidence may result from differences in definition, duration of follow-up, and the presence of both modifiable and nonmodifiable risks factors.[16] Major risk factors include African American, Hispanic, and South Asian ethnicity (compared with Caucasians or East Asians), obesity (defined as BMI greater than 30 kg/m^2), age older than 40 to 45 years, family history of diabetes among first-degree relatives, impaired glucose tolerance before transplantation or presence of other components of the metabolic syndrome, recipients of deceased donor kidneys, hepatitis C infection, and immunosuppressive therapy including corticosteroids; tacrolimus and to a lesser extent cyclosporine; and the mTOR inhibitors sirolimus and everolimus (Fig. 106-2).[16] Neither azathioprine (AZA) nor MMF is diabetogenic.

Other potential risk factors for the development of NODAT include the presence of certain human leukocyte antigens (HLAs)

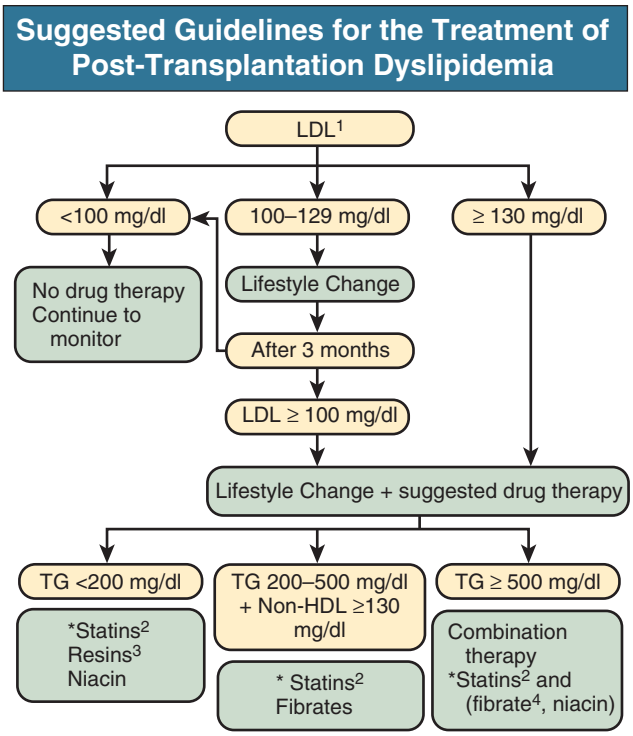

Figure 106-1 Suggested guidelines for the treatment of post-transplantation dyslipidemia. All transplant recipients should be regarded as CHD risk equivalent. Goals: LDL cholesterol below 100 mg/dl (optional <70 mg/dl[1]), TGs below 200 mg/dl, HDL above 40 to 50 mg/dl. *If LDL cholesterol targets not achieved with statin monotherapy, consider statins + cholesterol absorption inhibitor[5] combination. [1]LDL cholesterol below 70 mg/dl has been suggested for very-high-risk patients (NCEP, ATP III guidelines). [2]Statins are the most effective drugs and should be the agents of first choice. Start at low dose in patients on cyclosporine and tacrolimus. Monitor for myositis and transaminitis, particularly in those receiving combination therapy. [3]Coadministration of bile acid sequestrants and mycophenolic acid products is not recommended. [4]Extreme caution should be used with statin and fibrate combination therapy. *ATP III,* Adult Treatment Panel III; *CHD,* coronary heart disease; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *NCEP,* National Cholesterol Education Program; *TG:* triglyceride.

(such as A30, B27, and B42), increasing HLA mismatches, acute rejection history, cytomegalovirus (CMV) infection, male recipient, and male donor.[16] Polycystic kidney disease has been suggested to confer an increased risk of developing diabetes after kidney transplantation in some studies but not in others. Studies evaluating the association between genetic variations (single nucleotide polymorphism) and NODAT have been inconclusive. The findings of one single-center study suggest that new-onset hyperglycemia in the immediate postoperative period is predictive of future NODAT risk.[17]

Management of New-Onset Diabetes After Transplantation

In the general population, glycemic management in type 2 diabetes mellitus (T2DM) has become increasingly complex and often controversial because of the uncertain risks and benefits associated with intensive glycemic control and the widening array of pharmacologic agents available.[18] Both T2DM and NODAT are characterized by a relative or absolute impairment in insulin secretion, along with varying degrees of peripheral insulin resistance. In essence, NODAT resembles T2DM and it seems plausible to manage NODAT with a stepwise approach similar to that for patients with T2DM.

Patient-Centered Approach Medical management usually involves a multidisciplinary team approach involving patients (and frequently family members), transplant coordinators, transplant physicians, and diabetic educators. A shared decision-making approach whereby clinicians and patients mutually exchange information and reach a consensus on the therapeutic course of action is helpful.[18]

Target Hemoglobin A_{1c} Levels The 2011 American Diabetes Association's Standards of Medical Care in Diabetes recommend lowering hemoglobin A_{1c} (HbA_{1c}) to below 7.0% in most patients to reduce the incidence of microvascular disease. More stringent control (HbA_{1c} 6.0% to 6.5%) might be considered in a subset of patients with short disease duration, long life expectancy, and no significant CV disease, if this can be achieved without significant hypoglycemia or other treatment-related adverse effects.[18] For NODAT, the 2009 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines suggest a target A_{1C} level from 7.0% to 7.5%, not to fall below 6.0%, particularly if hypoglycemic reactions are

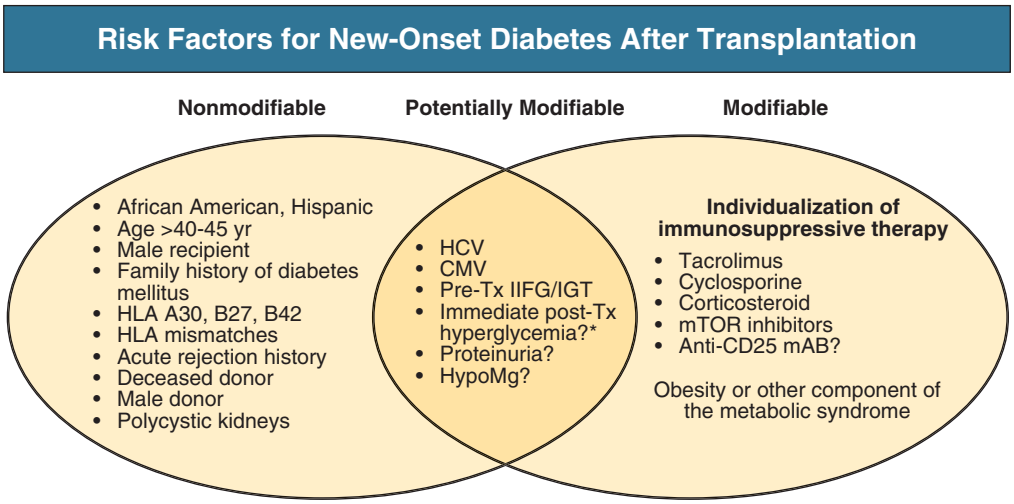

Figure 106-2 Risk factors for new-onset diabetes after transplantation (NODAT). *See text. *Anti-CD25 mAB,* anti-CD25 monoclonal antibody; *CMV,* cytomegalovirus; *HCV,* hepatitis C; *HLA,* human leukocyte antigen; *HypoMg,* hypomagnesemia; *IFG,* impaired fasting glucose; *IGT,* impaired glucose tolerance; *mTOR,* mammalian target of rapamycin; *Post-Tx,* post-transplant; *Pre-Tx,* pretransplant. *(Modified from reference 16.)*

common. In patients with diabetes, the use of low-dose aspirin (75 mg or 100 mg daily in Europe, 81 mg daily in the United States) for the primary prevention of CV disease should be based on patient preferences and values, balancing the risk of ischemic vascular events with the risk of bleeding.

Therapeutic Interventions

Nonpharmacologic Management The effect of lifestyle modification to prevent or delay the progression of post-transplantation impaired glucose to overt NODAT has not been studied. A small cross-sectional and observational study showed that higher levels of physical activity were associated with a lower risk of abnormal glucose tolerance and obesity in kidney transplant recipients. In contrast, individuals with limited physical activity consistently showed higher rates of abnormal glucose tolerance and central obesity.[19] Because higher pretransplant BMI correlates with insulin resistance after transplantation, obesity treatment seems to be a reasonable target for intervention.[20]

We recommend promoting lifestyle modification in kidney transplant recipients, including moderation of dietary sodium (<2400 mg sodium per day) and saturated fat intake (<7% calories from saturated fats, 2% to 3% calories from *trans*-fatty acids), regular aerobic exercise, and weight reduction. Carbohydrate intake should be limited to 50% to 60% of caloric intake. The American Heart Association guidelines in non–transplant recipients also suggest intake of at least 25 g of dietary fiber per day and two servings of fish per week. Defining realistic goals such as a target weight loss of 5% to 10% of total body weight and a patient-centered approach to education may be invaluable in achieving success.

Modification of immunosuppression should be considered in high-risk patients. Corticosteroid dose reduction significantly improves glucose tolerance during the first year after transplantation. However, any dose reduction should be weighed against the risk of acute rejection. A corticosteroid-sparing regimen or corticosteroid avoidance protocol should be individualized. Tacrolimus-to-cyclosporine conversion therapy in patients who fail to achieve target glycemic control or in those with difficult-to-control diabetes has yielded variable results. At the authors' institution, tacrolimus-treated patients who develop NODAT are often switched to cyclosporine. Conversion therapy has resulted in variable improvement in glycemic control and should be considered in such patients. However, mycophenolate exposure is lower with cyclosporine than with tacrolimus immunosuppression; hence mycophenolate dosage adjustment or drug level monitoring may be necessary.

Pharmacologic Treatment Orally administered agents are often required to treat NODAT. Although oral hypoglycemic agents may be effective, insulin therapy may be necessary in up to 40% of patients, particularly in the early post-transplantation period.

Metformin is preferred for overweight patients but is contraindicated in patients with a GFR below 50 ml/min because in such patients it can cause lactic acidosis. Sulfonylureas should be titrated slowly for patients with reduced GFR or in elderly patients because of the increased risk of hypoglycemia. In these patients, it is best to start with a low dose and titrate upward every 1 to 2 weeks. Sulfonylureas may also be associated with modest weight gain and secondary failure rate from exacerbation of islet dysfunction.[18] The nonsulfonylurea meglitinides are insulin secretagogues with a mechanism of action similar to that of the sulfonylureas. They have a more rapid onset and shorter duration of action and seemingly a lower risk of hypoglycemia and lower weight gain. These agents are therefore best suited for patients whose food intake is erratic, elderly patients, and patients with impaired graft function. They are best taken before meals, and the dose may be omitted if a meal is skipped.

The thiazolidinedione (TZD) derivatives are insulin sensitizers that may allow for a reduction in insulin requirement. They do not increase the risk of hypoglycemia and may have a more durable effect than sulfonylureas or metformin.[18] Potential adverse effects of these agents include weight gain, peripheral edema, anemia, pulmonary edema, congestive heart failure, and increased fracture risks. The incidence of peripheral edema is increased when TZDs are used in combination with insulin. Rosiglitazone has been removed from the market because of the concerns of increased myocardial infarction risk. More recently, pioglitazone has been reported to be associated with a possible risk of bladder cancer.[18]

Glucagon-like peptide 1 (GLP-1) analogues and dipeptidyl peptidase–4 (DDP-4) inhibitors are incretin-based agents that amplify the effects of naturally occurring GLP-1. In contrast to insulin and most other glucose-lowering agents that cause weight gain or hypoglycemia, GLP-1 inhibitors and DDP-4 inhibitors have a favorable or neutral effect on weight reduction and no inherent risk of hypoglycemia. Concerns regarding an increased risk of pancreatitis and pancreatic cancer associated with the use of GLP-1 receptor agonists remain unresolved.

Routine recommendations include measurement of HbA_{1c} level every 3 months and regular screening for diabetic complications including microalbuminuria, retinopathy, and polyneuropathy with associated lower extremity ulcerations and infections. Fasting lipid profile should be measured annually. In transplant recipients with multiple CV disease risk factors, more frequent monitoring of lipid profile should be performed at the discretion of the clinicians. Box 106-1 provides guidelines for the management of NODAT. Of note, HbA_{1c} cannot be accurately interpreted within the first 3 months after transplantation because anemia and impaired graft function can directly interfere with the HbA_{1c} assay. Recent blood transfusion or the use of dapsone may also alter HbA_{1c} levels.

Cigarette Smoking

Smoking by donor or recipient may affect outcomes after solid organ transplantation.[21] A history of smoking in kidney donors has been shown to be associated with decreased graft and recipient survival.[21]

As in the general population, cigarette smoking is associated with increased CV disease morbidity and mortality in kidney transplant recipients. Smoking cessation 5 years before transplantation reduces the risk of death by 29%.[22] Every effort should be made to encourage patients to quit smoking. A multifaceted approach including behavioral and pharmacologic strategies appears to be most effective.

Obesity

Obesity at transplantation (defined as BMI ≥30 kg/m^2) has a reported prevalence of 9.5% to 29%, and its prevalence among transplant recipients in the United States doubled between 1987 and 2001. A high BMI at transplant is a significant independent predictor of congestive heart failure and atrial fibrillation.[23] The impact of BMI on cardiac-related death follows a U-shaped risk, with an adjusted risk of cardiac death increased at both low and high BMI compared with a reference group with a BMI of 22 to 24 (with a hazard ratio [HR] of 1.3 for BMI <20; HR 1.2 for BMI 30 to 32; HR 1.4 for BMI >36).[24]

Management of post-transplantation obesity includes lifestyle and dietary modification. Corticosteroid reduction or withdrawal must be balanced against the risk of graft rejection and graft loss. The use of pharmacologic agents for weight reduction in the post-transplantation period is currently not recommended because of unknown potential drug-drug interactions.

Management of New-Onset Diabetes After Transplantation

Dietary Modification

- Dietician referral.
- For diabetic dyslipidemia: A diet low in saturated fats and cholesterol and high in complex carbohydrates and fiber is recommended.
- The AHA* guidelines suggest limiting cholesterol (<200 mg/day for those with diabetes mellitus); less than 7% of calories from saturated fats; 2% to 3% of calories from *trans*-fatty acids; and 2400 mg or less of sodium per day. More than 25 g of dietary fiber per day and two servings of fish per week are also recommended.

Lifestyle Modifications

- Exercise
- Weight reduction or avoidance of excessive weight gain
- Smoking cessation

Adjustment or Modification in Immunosuppressive Medications†

- Rapid corticosteroid taper, corticosteroid-sparing or corticosteroid-avoidance protocols
- Tacrolimus to cyclosporine conversion

Pharmacologic Therapy

- Acute, marked hyperglycemia (may require inpatient management)
- Insulin therapy (consider insulin drip when glucose is 400 mg/dl or higher)
- Chronic hyperglycemia: target HbA_{1c} 7.0% to 7.5%, not to fall below 6.0% (see text)
- Oral glucose-lowering agent monotherapy or combination therapy‡ and/or insulin therapy
- Consider diabetologist referral if HbA_{1c} remains at 9.0% or higher

Monitoring of Patients with NODAT

- HbA_{1c} every 3 months
- Screening for microalbuminuria
- Regular ophthalmologic examination
- Regular foot care
- Annual fasting lipid profile
- Aggressive treatment of dyslipidemia and hypertension

Box 106-1 Management of new-onset diabetes after transplantation (NODAT). *American Heart Association. †Clinicians must be familiar with the patient's immune history before manipulating immunosuppressive therapy. ‡The choice of a particular agent should be based on the characteristics of each individual patient (see text). *(Modified from reference 2.)*

Data are inadequate regarding the safety and efficacy of post-transplantation gastric bypass surgery or adjustable gastric banding in ameliorating comorbid conditions such as hypertension, diabetes mellitus, and dyslipidemia. In an analysis of the United States Renal Data System (USRDS) database, mortality rates in patients undergoing gastric bypass surgery after transplantation were higher compared with those without kidney disease who had undergone the same surgery. Nonetheless, the difference in mortality rates was thought to be within "acceptable range" and attributed to poor wound healing associated with the use of immunosuppressive therapy. In a small series of five patients (mean age 40.8 years; mean BMI 52.2) who underwent laparoscopic bariatric surgery after kidney transplantation, there were no postoperative complications and the percent of excess weight loss at 2 years was over 50% in all patients.[25] With the refinement in surgical techniques and advancement in postoperative care, post-transplantation bariatric surgery for morbid obesity should be explored.

Aspirin and Antiplatelet Therapies

Aspirin is widely used to reduce CV events in nontransplant patients. Among patients with a functioning graft at 1 year, the use of antiplatelet medications in the first year after transplantation was also associated with a 27% lower risk of major cardiac events at 5 years.[7]

Unconventional Cardiovascular Disease Risk Factors

Proteinuria

Proteinuria occurs in 9% to 40% of kidney transplant recipients with a functioning graft. Proteinuria from native kidneys typically decreases rapidly after transplantation, whereas worsening proteinuria frequently suggests allograft pathology. As in the nontransplant setting, post-transplantation proteinuria increases the risk of CV events, graft loss, and mortality. Controlled trials evaluating the beneficial effect of treating proteinuria in reducing CV risk in kidney transplant recipients are lacking. The Canadian randomized double-blind controlled trial evaluating the effect of ramipril versus placebo in kidney transplant recipients with proteinuria and an eGFR of 20 to 55 ml/min/1.73 m^2 is anticipated to complete enrollment by the end of 2014. While the routine recommendations regarding ACE inhibitor or ARB use for the treatment of proteinuria after kidney transplant await results of controlled trials, ACE inhibitors or ARBs should be considered in transplant recipients with proteinuria because of their well-established antiproteinuric and cardioprotective effects. The 2009 KDIGO clinical practice guidelines recommend ACE inhibitors or ARBs as first-line therapy for patients with hypertension and documented proteinuria of 1 g/day or more.

Cardiac Troponin T

Cardiac troponin T (cTnT) has been recently proposed to provide prognostic information in the cardiac evaluation of patients with end-stage renal disease (ESRD). Increased levels of cTnT correlate with all-cause and cardiac death risk in asymptomatic patients with ESRD, and higher pretransplant cTnT was associated with increased risk of post-transplant death and cardiac events independent of CV risk factors. Although cTnT levels decline rapidly after transplant, patients in whom cTnT do not fall to normal have a high risk of death or cardiac events.[26] Therefore, persistently elevated cTnT levels in the pretransplant and post-transplant period can be used to define a target population for CV risk modification or intervention programs.

COMMON LABORATORY ABNORMALITIES

Anemia

In the immediate post-transplantation period, aggressive perioperative volume expansion may result in dilutional anemia. Refractory or severe anemia mandates aggressive evaluation to exclude the possibility of surgical postoperative bleeding, particularly in those with a rapid fall in hemoglobin and hematocrit levels.

Mild anemia is common in the early post-transplantation period when erythropoietin (EPO) therapy is typically discontinued, but usually improves within several weeks to months. Suggested etiologic factors for post-transplantation anemia include iron deficiency, impaired graft function, acute rejection episodes, recent infection, and medications (such as AZA, MMF, sirolimus, everolimus, and

ACE inhibitors and ARBs). Anemia has also been reported to be more common in African American and female transplant recipients.

Assessment of baseline iron stores at the time of transplantation may be invaluable because iron deficiency is not uncommon in the dialysis population. Profound iron deficiency should be treated with intravenous iron as tolerated. EPO therapy and darbepoetin alfa are effective in the treatment of anemic kidney transplant recipients. Although the 2009 Kidney Disease Outcomes Quality Initiative (KDOQI) anemia guidelines recommend a target hemoglobin level of 11 to 13 g/dl for patients with CKD, high hemoglobin and high epoetin doses in large CKD anemia trials demonstrated a possible harmful effect. Furthermore, observational studies in kidney transplant recipients suggested that mortality may be increased with hemoglobin levels above 12.5 g/dl. Although evidence-based recommendations await the result of large randomized trials comparing the safety and efficacy of EPO-stimulating agents versus placebo, management of post-transplantation anemia to keep hemoglobin level in the range of 10 to 12 g/dl seems plausible.

Refractory anemia or anemia that fails to rise gradually to a normal or near-normal level after the first few post-transplantation weeks can be a result of occult gastrointestinal bleeding, tertiary hyperparathyroidism, underlying inflammatory conditions, or parvovirus B19 infection. Sirolimus or everolimus, AZA, MMF, and other commonly used drugs including ACE inhibitors and ARBs may cause or exacerbate anemia and should not be overlooked. EPO-resistant anemia has been described in patients receiving sirolimus immunosuppression. In stable kidney transplant recipients, conversion from sirolimus to enteric-coated MMF may help resolve anemia. Although uncommon, drug-induced hemolysis from agents including dapsone or other causes of hemolysis should also be considered.

Leukopenia and Thrombocytopenia

Leukopenia and thrombocytopenia are most commonly related to adverse drug effects from agents including AZA, antilymphocyte antibody treatment, MMF, sirolimus, everolimus, and trimethoprim-sulfamethoxazole, among others. Withholding of the offending agent or dose reduction generally corrects these hematologic abnormalities. Severe leukopenia may be safely treated with granulocyte-stimulating factor. Thrombotic microangiopathy (TMA) or CMV infection should be excluded. Parvovirus B19 infection may present with refractory anemia, pancytopenia, and TMA. An increase in the incidence of leukopenia was found in transplant recipients receiving alemtuzumab induction. Other hematologic adverse effects of alemtuzumab include anemia, lymphopenia, and thrombocytopenia. Alemtuzumab-induced aplastic anemia has also been reported in the postmarketing phase. Bortezomib, a novel first-in-class proteasome inhibitor recently introduced into clinical transplantation for the treatment of antibody-mediated rejection and desensitization protocols, has been shown to cause leukopenia and thrombocytopenia. The risk of thrombocytopenia is increased in patients with baseline low-platelet counts

Erythrocytosis

Post-transplant erythrocytosis (PTE) occurs in 8% to 25% of transplant recipients within the first 2 years. The incidence of PTE appears to have decreased in recent years, ascribed to more frequent use of ACE inhibitors and ARBs. Risk factors for PTE include the presence of native kidneys, male gender, excellent graft function and the absence of rejection episodes, high baseline hemoglobin before transplant, and hypertension. Smoking and diabetes have been shown to be risk factors for PTE in some but not all studies. Other suggested risk factors include polycystic kidney disease and GN as the cause of ESRD. Transplant renal artery stenosis has not been consistently shown to be a risk factor for PTE. Both hormonal systems and growth factors have been implicated in the pathogenesis of PTE. These may include defective feedback regulation of EPO metabolism, direct stimulation of erythroid precursors by angiotensin II, abnormalities in levels of circulating insulin-like growth factor 1 (IGF-1) and its binding proteins, and an increase in serum-soluble stem cell factors, which stimulates the growth of erythroid progenitor cells. Serum-soluble stem cell factors have been shown to correlate with both hematocrit values and with the observed and expected EPO values in kidney transplant recipients with PTE.[27]

Treatment is generally recommended for a hemoglobin level exceeding 17 to 18 g/dl or a hematocrit level over 51% to 52% because of the associated risk of thromboembolic complications, hypertension, and headaches. Treatment with ACE inhibitors or ARBs is often sufficient, although phlebotomy may occasionally be necessary. A negative association between the use of sirolimus and PTE has been reported. Nonetheless, modification of immunosuppressive medications to treat PTE has generally not been done in clinical practice.

Hyperkalemia

Mild hyperkalemia is commonly encountered in kidney transplant recipients particularly in the early post-transplantation period with higher doses of CNI. It is often associated with mild hyperchloremic acidosis, a clinical presentation reminiscent of type 4 renal tubular acidosis. Suggested mechanism(s) of CNI-induced hyperkalemia include hyporeninism hypoaldosteronism, aldosterone resistance, and inhibition of cortical collecting duct potassium secretory channels. Cyclosporine has been shown to decrease Na^+,K^+-ATPase activity in K^+ secretory cells in the cortical and outer medullary collecting tubules, thereby decreasing intracellular K^+ accumulation required for urinary secretion. In patients receiving cyclosporine or tacrolimus immunosuppression, a potassium level in the range of 5.2 mmol/l to 5.5 mmol/l is typically seen. Higher potassium levels, especially in the presence of concomitant use of drugs that may exacerbate hyperkalemia such ACE inhibitors, ARBs, and β-blockers, may require their discontinuation. Caution is needed when potassium-containing phosphorus supplements are prescribed. Although trimethoprim can cause hyperkalemia via an amiloride-like effect, the routine use of low-dose trimethoprim-sulfamethoxazole prophylactic therapy is rarely the cause of severe or refractory hyperkalemia in kidney allograft recipients. Finally, because efficient renal potassium secretion requires good urine flow, urinary obstruction must also be considered in the presence of hyperkalemia. Treatment of hyperkalemia is discussed in Chapter 9. Sodium polystyrene sulfonate (Kayexalate) or calcium resonium enemas should be avoided in the early post-transplantation period to avoid colonic dilation and perforation.

Hypokalemia

Sirolimus may be associated with hypokalemia. Hypokalemia has been reported in 34% and potassium supplementation was required in 27% of patients treated with sirolimus.[28] Sirolimus-induced increased tubular secretion of potassium has been suggested as a possible mechanism.[29] Furosemide is frequently used in the early

post-transplantation period, and hence diuretic-induced hypokalemia should also not be overlooked.

Hypophosphatemia

Hypophosphatemia is frequently encountered in the first months after transplantation. Concomitant hypercalcemia suggests post-transplantation hyperparathyroidism. In the absence of hypercalcemia, renal phosphate wasting syndrome or malnutrition should be considered. Early after transplantation, hypophosphatemia has been attributed to a massive initial diuresis, particularly after a living-donor kidney transplant, defective renal phosphate reabsorption caused by ischemic injury, glucosuria (caused by hyperglycemia-induced osmotic diuresis), magnesium depletion, and corticosteroid use—the latter by inhibiting proximal tubular reabsorption of phosphate. There has been increasing evidence suggesting that fibroblast growth factor 23 (FGF-23) plays a major contributory role in the development of early post-transplantation hypophosphatemia independent of parathyroid hormone (PTH) level. FGF-23 is a phosphaturic hormone and its levels are increased in the early stages of CKD and significantly elevated in dialysis patients. Pretransplant FGF-23 was found to be the main predictor of post-transplant phosphate levels.[30] In contrast to hypophosphatemia occurring in the early post-transplant period, persistent hypophosphatemia beyond 1 year after transplant has been attributed mainly to persistent hyperparathyroidism rather than to increased FGF-23 levels.

Hypercalcemia

Hypercalcemia is common after transplantation and is generally a result of persistent secondary hyperparathyroidism. The concomitant presence of severe hypophosphatemia, particularly in patients with excellent graft function, may exacerbate hypercalcemia through stimulation of renal proximal tubular 1α-hydroxylase. Resolution of soft tissue calcifications, high-dose corticosteroid therapy, and immobilization are potential contributing factors. In about two thirds of patients, hypercalcemia resolves spontaneously within 6 to 12 months. However, spontaneous resolution occurs in less than half of those whose hypercalcemia existed before transplantation. Persistent hyperparathyroidism has generally been attributed to continued autonomous production of PTH from nodular hyperplastic glands, reduced density of calcitriol receptors, and decreased expression of the membrane calcium sensor receptors that render cells more resistant to physiologic concentrations of calcitriol and calcium. Persistently elevated FGF-23 levels after transplant may contribute to persistent hyperparathyroidism through inhibition of 1α-hydroxylase activity leading to low calcitriol levels. The risk of persistent hyperparathyroidism is increased with the duration of dialysis and the severity of pretransplant hyperparathyroidism. Severe hypercalcemia or persistent hypercalcemia (≥12 months) requires further evaluation. Initial assessment should include an intact PTH level. Imaging studies, including neck ultrasound or parathyroid technetium 99m (^{99m}Tc)–sestamibi scan, are required to determine if the clinically observed hyperparathyroidism arises from parathyroid adenoma or parathyroid gland hyperplasia, or hyperplastic nodular formation of the parathyroid glands.

Early studies demonstrated that cinacalcet, a calcimimetic drug, reduces serum calcium in kidney transplant recipients with hypercalcemic hyperparathyroidism. However, with the increasing use of cinacalcet, cinacalcet-induced nephrocalcinosis and graft failure have been reported.[31] Parathyroidectomy is warranted in patients with tertiary hyperparathyroidism or persistent severe hypercalcemia (>11.5 to 12 mg/dl [2.87 to 3.0 mmol/l]) for longer than 6 to 12 months, symptomatic or progressive hypercalcemia, nephrolithiasis, persistent metabolic bone disease, calcium-related renal allograft dysfunction, or progressive vascular calcification and calciphylaxis.[32] In a retrospective cohort study of 83 kidney transplant recipients with tertiary hyperparathyroidism, parathyroidectomy resulted in a lower serum calcium level (9.28 mg/dl) compared with cinacalcet (10.20 mg/dl) ($P < .01$) at 6 weeks. The highest pretreatment calcium level was higher in patients treated with parathyroidectomy compared with cinacalcet (12.2 vs. 11.7 mg/dl, $P < .01$). One fourth of the "observation" group showed persistent hypercalcemic symptoms, compared with 7.7% in the cinacalcet and 0% in the parathyroidectomy group ($P < .01$).[33] Whether calcimimetics confer better normalization of biochemical parameters and obviate the need for parathyroidectomy remains to be determined. Furthermore, clinicians should remain vigilant for the potential development of nephrocalcinosis associated with the use of cinacalcet.

Hypomagnesemia

Cyclosporine, tacrolimus, and sirolimus can cause hypomagnesemia by inducing urinary magnesium wasting. Other factors that may contribute to post-transplantation hypomagnesemia include loop diuretic therapy, recovery from acute tubular necrosis, post–obstructive polyuria status, and renal tubular acidosis. Hypomagnesemia may be more common in diabetics. In the first 3 months after transplantation, a magnesium level below 1.5 mg/dl (0.62 mmol/l) is common. Dietary magnesium intake is usually insufficient, and high-dose oral magnesium supplementation (i.e., 400 to 800 mg magnesium oxide three times a day) may be required. Intravenous magnesium should be considered in patients with severe hypomagnesemia (<1.0 mg/dl or 0.41 mmol/l), particularly patients with a prior history of CHD or cardiac arrhythmias and those taking digoxin. Aggressive treatment of hypomagnesemia reduces cyclosporine-induced neurotoxicity and may enhance blood pressure control.

Abnormal Liver Function Tests

Elevation of hepatic enzymes is common in the early post-transplantation period and is generally caused by drug-related toxicity. Potential culprits include acyclovir, ganciclovir, trimethoprim-sulfamethoxazole, cyclosporine, tacrolimus, sirolimus, everolimus, statin therapy, and proton pump inhibitors. Cyclosporine and less commonly tacrolimus may cause transient, self-limited, dose-dependent elevations of transaminase levels and mild hyperbilirubinemia secondary to defective bile secretion. Elevated liver enzymes caused by drug-related adverse effects generally improve or resolve after drug discontinuation or dose reduction.

Persistent or profound elevation in hepatic liver enzymes should prompt further evaluation to exclude infectious causes including CMV, hepatitis B virus (HBV), and hepatitis C virus (HCV). In high-risk candidates for primary CMV infections (recipient seronegative, donor seropositive), it may occasionally be necessary to initiate CMV therapy pending laboratory results, particularly when there is a high index of clinical suspicion (fever, fatigue, malaise, gastroenteritis, leukopenia or thrombocytopenia). Evidence of post-transplant HBV reactivation (elevated alanine transaminase (ALT), histologic hepatitis, and serum DNA $>10^5$ copies/ml) should be treated with lamivudine or the newer nucleoside analogue entecavir. Some programs routinely initiate antiviral prophylaxis in all hepatitis B surface antigen (HBsAg)–positive candidates at the time of transplantation. Pretransplantation antiviral prophylactic therapy is recommended in

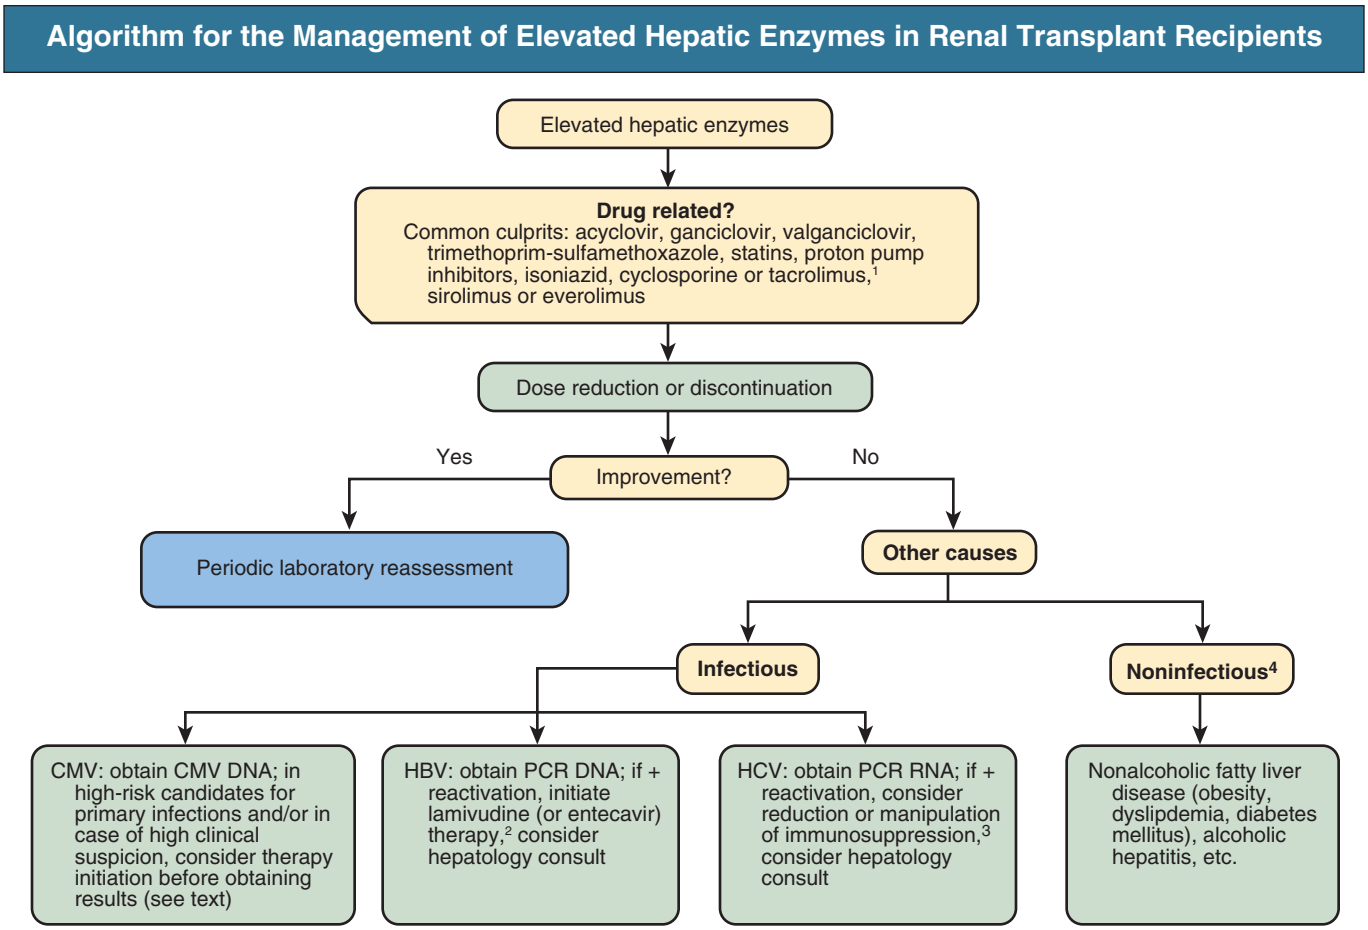

Figure 106-3 Algorithm for the management of elevated hepatic enzymes in kidney transplant recipients. [1]Cyclosporine and less commonly tacrolimus may cause transient, self-limited dose-dependent elevations of aminotransferase levels and mild hyperbilirubinemia secondary to defective bile secretion. [2]Some programs routinely commence antiviral prophylactic therapy in all HBsAg-positive candidates at the time of transplantation. [3]There is currently no effective treatment for chronic hepatitis C in kidney transplant recipients (see text). [4]Appropriate evaluation and management similar to nontransplant settings. *CMV,* Cytomegalovirus; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *PCR,* polymerase chain reaction.

kidney transplant candidates who have HBV DNA exceeding 10^5 copies/ml and active liver disease defined as ALT more than two times the upper limit of normal or biopsy-proven hepatic disease. Suppression of HBV replication with nucleotide analogues has been suggested to improve the survival of HBV-infected kidney transplant recipients.[34] There is currently no effective treatment for chronic hepatitis C in kidney transplant recipients. Although treatment with interferon-α may result in clearance of HCV RNA in 25% to 50% of patients, rapid relapse after drug withdrawal is nearly universal. More important, interferon-α treatment has been shown to precipitate acute allograft rejection and graft loss and is currently not routinely recommended for kidney transplant recipients with HCV infection. Its use should be individualized at the discretion of the transplant nephrologist and hepatologist. Studies evaluating interferon-free regimens showed promising results. At present, the management of HCV infection in this patient population should probably rely on manipulation of immunosuppressive therapy. Experiences gained from liver transplantation indicate that corticosteroid therapy and antilymphocyte antibody treatment are associated with enhanced viral replication and more rapid progression to cirrhosis. Based on these observations, it is advisable to avoid antilymphocyte antibody induction therapy and minimize corticosteroid dosage in transplant recipients with chronic HCV infection. A suggested algorithm for the management of kidney transplant recipients with elevated hepatic enzymes is shown in Figure 106-3.

BONE AND MINERAL METABOLISM AFTER TRANSPLANTATION

Post-transplantation Bone Disease

Post-transplantation bone disease is a common and complex complication after kidney transplantation because of the adverse effects of immunosuppression, mainly with corticosteroids, hypophosphatemia, and disturbances in the FGF-23–PTH–vitamin D axis. Corticosteroids act on the skeletal system by directly inhibiting osteoblastogenesis and inducing apoptosis of osteoblasts and osteocytes, and by increasing bone resorption through osteoclast activation. Other adverse effects of corticosteroids on bone mechanical integrity include inhibition of intestinal calcium absorption, enhancement of renal calcium excretion, and direct suppression of gonadal hormone secretion. Low plasma calcidiol 25(OH) vitamin D level may also contribute to bone disease and is very common in kidney transplant recipients, with a reported prevalence of calcidiol deficiency of 30% and insufficiency of 81%. Suggested causative factors include nutritional deficiency, malabsorption, decreased sun exposure, and increased metabolism of calcidiol to calcitriol after a successful kidney transplant.

Other factors that have been suggested to contribute to post-transplantation bone loss include "normal" age-dependent osteoporosis, persistent metabolic acidosis, phosphate depletion, diabetes

mellitus, hypogonadism, and smoking. Experimental animal models suggest that CNIs may contribute to post-transplantation bone loss by stimulating bone resorption. However, *in vivo* studies show that CNIs may increase bone resorption, leading to bone formation.[35] Sirolimus may interfere with the proliferation and differentiation of osteoblasts, but more important, it inhibits osteoclast formation. One small European study showed that sirolimus decreased serum level of bone resorption markers in patients treated with sirolimus compared with those receiving a CNI-based regimen.[36] Everolimus may also inhibit bone resorption and prevent bone loss based on experimental studies.[37] The effects of mTOR inhibitors on post-transplantation bone disease remain unclear.

Osteoporosis

Post-transplantation decline in bone marrow density (BMD) is most pronounced in the first 6 months and correlates with higher corticosteroid exposure in the early post-transplantation period. This early rapid decrease in BMD is usually followed by a slower rate of bone loss, which reflects cumulative corticosteroid dose. BMD has been reported to decrease at a mean of 5.5% to 19.5% during the first 6 months after transplant, 2.6% to 8.2% from months 6 to 12, and 0.4% to 4.5% thereafter.[38] Controversy exists as to whether bone loss continues to decline, stabilizes, or even reverses after the first year. A decrease in BMD averaging 1.7% per year in later post-transplant years has been reported by some, whereas stabilization during the second year, followed by an improvement of 1% to 2% per year thereafter has been observed by others. Limited bone biopsy studies in kidney transplant recipients demonstrated that low-turnover bone disease including adynamic bone and osteomalacia are common.[38] However, larger studies involving bone biopsies to better assess the combined effects of pretransplantation renal osteodystrophy and post-transplantation bone disease associated with immunosuppression are needed.

Evaluation of patients for bone loss or osteoporosis relies on the measurement of BMD using dual energy x-ray absorptiometry (DXA) scan. In kidney transplant recipients with an eGFR over 30 ml/min/1.73 m^2, the KDIGO guidelines suggest BMD measurement in the first 3 months after transplant if patients receive corticosteroids or have risk factors for osteoporosis as in the general population (low quality of evidence). In patients in the first 12 months after transplant with an eGFR exceeding 30 ml/min/1.73 m^2 and low BMD, the KDIGO guidelines suggest that consideration should be given to treatment with vitamin D, calcitriol or alfacalcidol, or bisphosphonates (low quality of evidence). In transplant recipients with CKD stage 4 or 5, the KDIGO guidelines do not recommend routine BMD screening because it does not predict fracture risk as it does in the general population. It should be noted that in the setting of combined osteoporosis and CKD, DXA may be completely misleading. For instance, adynamic bone disease, mild hyperparathyroidism, and genuine osteoporosis may yield the same BMD, yet therapy is very different. Hence, BMD can be interpreted only in the clinical and laboratory settings, and bone biopsy should be performed if uncertainty arises.

Avascular Necrosis

Post-transplantation osteonecrosis (avascular necrosis [AVN]) occurs with an incidence of 3% to 16% and most commonly affects the femoral head and neck. AVN usually occurs within the first few years after transplantation and may affect other joints including the knees, the shoulders, and less commonly the ankles, elbows, and wrists. Predisposing factors for the development of AVN include greater exposure to intravenous corticosteroid pulse therapy, low bone mass, hyperparathyroidism, increasing dialysis duration, excessive weight gain, hyperlipidemia, microvascular thrombosis, and a history of local trauma. Studies in kidney transplant recipients maintained on a corticosteroid-free immunosuppressive regimen demonstrated low rates of AVN at 3-year follow-up.[39] Cyclosporine has also been suggested to increase the risk of osteonecrosis because of its vasoconstrictive effect.

Early AVN of the femoral head commonly presents with hip or groin pain or referred knee pain. Symptoms may be aggravated by weight bearing but may also be paradoxically worse at night. Magnetic resonance imaging is the most sensitive technique for early detection. Plain radiographs are of limited diagnostic value in the early stage. Use of crutches to avoid weight bearing on the affected side and orthopedic referral are advisable. Drastic corticosteroid dose reduction or discontinuation has little if any effect on altering the course of established AVN and may jeopardize graft function.

Prevention and Management of Post-transplantation Bone Diseases

Management of post-transplantation bone disease has largely been based on studies involving postmenopausal osteoporosis and corticosteroid-induced osteopenia in nontransplant settings. Limited studies in solid organ transplantation have yielded variable and conflicting results, in part because of the complex pathophysiology of bone and mineral metabolism after transplantation, particularly in recipients of kidney transplants. Nonetheless, preventive measures to minimize post-transplantation bone loss should be initiated early after transplantation. Early ambulation and physical exercise should be encouraged. Adequate calcium supplementation (1000 mg/day) in nonhypercalcemic patients is recommended in the first post-transplantation year to prevent rapid bone loss resulting from corticosteroid-induced decreased intestinal calcium absorption. The KDIGO practice guidelines recommend measuring calcidiol levels and correcting vitamin D deficiency and insufficiency with use of treatment strategies recommended for the general population. In patients at increased risk for fracture, consideration should be given to rapid corticosteroid withdrawal or corticosteroid-free immunosuppressive protocols after weighing the risks and benefits of acute rejection. High pretransplantation PTH levels predict persistent hyperparathyroidism after transplantation, which may contribute to bone loss after transplantation. Hence, preexisting hyperparathyroidism associated with CKD should be treated according to the KDOQI guidelines.

In patients with preexisting secondary hyperparathyroidism, hypercalcemia and hypophosphatemia may develop after a successful kidney transplant because of the combined effect of persistent hyperparathyroidism and the newly elevated calcitriol level. The contributory role of FGF-23 in the development of post-transplant hypophosphatemia was previously discussed. Conservative management with phosphate replacement and suppression of hyperparathyroidism with cinacalcet has generally been recommended. Although no guidelines exist, phosphate supplementation should be considered in patients with a phosphate level below 1.5 mg/dl (0.5 mmol/l) to avoid complications associated with severe hypophosphatemia (e.g., rhabdomyolysis, left ventricular dysfunction, respiratory muscle weakness, and hemolysis). However, overaggressive phosphate replacement is not recommended because it can result in hypocalcemia, persistent hyperparathyroidism, hyperphosphatemia, and calcitriol deficiency and increase the risk of nephrocalcinosis and acute phosphate nephropathy.[35] Various forms of vitamin D derivatives with or without calcium supplementation have been used by independent investigators with variable improvement in post-transplantation bone and mineral parameters including serum calcium, phosphorus, PTH, and alkaline phosphatase.[38] Cinacalcet

is currently used off-label by most U.S. centers to treat hypercalcemia associated with persistent hyperparathyroidism.

Bisphosphonates increase BMD in postmenopausal women and patients with corticosteroid-induced osteoporosis, particularly at the lumbar spine and trochanter. Studies in kidney transplant recipients similarly show that bisphosphonates significantly improve BMD at the lumbar spine and femoral neck and may reduce fracture risk.[40] In a meta-analysis of randomized controlled trials, treatment with bisphosphonates or vitamin D reduced the number of patients with fracture (odds ratio [OR] 0.50 [95% confidence interval (CI), 0.29-0.83]) and the number of vertebral fractures (OR 0.24 [95% CI, 0.07-0.78]). An increase in BMD at the lumbar spine (2.98% [95% CI 1.31-4.64]) and femoral neck (3.05% [2.16, 3.93]) was also observed. When bisphosphonate trials were examined separately, there was a reduction in the number of patients with fractures (OR 0.53 [0.30, 0.91]), whereas no significant reduction in vertebral fractures was observed.[40] However, the beneficial effects of bisphosphonate therapy in the post-transplantation period have recently been questioned. In a randomized, controlled, double-blind trial of 129 renal transplant recipients with early stable renal function, the addition of ibandronate therapy to a regimen of calcitriol 0.25 μg/day and calcium 500 mg bid showed no significant difference in lumbar spine BMD at 12-month follow-up. Lumbar spine BMD was increased in both groups. There was a small overall decline in BMD of 0.5% in the femur and 1.9% at the radius in the placebo group.[41] It is speculated that the stability in BMD was mainly a result of the efficacy of calcitriol and calcium.

Calcitonin inhibits osteoclastic action by a direct receptor-mediated signal. Similar to bisphosphonates, calcitonin has been shown to be effective in postmenopausal patients as well as patients with corticosteroid-induced osteoporosis. However, the beneficial effects of calcitonin on bone loss have not consistently been shown in the transplant setting. Furthermore, calcitonin has been shown to have no effect on fracture risk in kidney transplant recipients.

Teriparatide is a recombinant human PTH that has been shown to exert anabolic effects on the skeleton when given intermittently. In one single-center study, teriparatide administered to transplant patients for 6 months showed no change in BMD in the lumbar spine or distal radius compared with placebo. However, femoral neck BMD remained stable in teriparatide-treated group but was significantly decreased in the placebo group.[42] There are currently insufficient data to recommend teriparatide use in kidney transplant recipients.

Hormone deficiencies have also been suggested to contribute to bone loss after transplantation. Estrogen or androgen deficiency may persist after transplantation. Limited studies have shown that estrogen replacement therapy improves BMD in postmenopausal liver, lung, and bone marrow transplant recipients. To date, there have been no data to support or refute the use of hormonal therapy to prevent post-transplantation–related bone loss in postmenopausal women; hence treatment should be individualized. The association of hormonal therapy and CV risk should not be overlooked. Testosterone deficiency has also been implicated in the development of bone loss and fractures after transplantation. However, the role of hormonal replacement therapy in men with hypogonadism is not well defined. Because of its potential side effects, including dyslipidemia, hepatic enzyme abnormalities, erythrocytosis, and prostatic hypertrophy, testosterone should probably be given only to men with true hypogonadism.

In summary, vitamin D analogues and bisphosphonates are the most consistently effective agents for the prevention and treatment of bone and mineral bone disorders in recipients of solid organ transplants. However, with the recent findings of a lack of significant beneficial effect of bisphosphonate therapy compared with calcitriol and calcium therapy alone,[41] and the potential for bisphosphonate to oversuppress bone metabolism, its use in the post-transplantation setting should best be individualized. In our opinion, bisphosphonate therapy may be justifiable in high-risk individuals including those with preexisting osteoporosis or documented overall low bone mass, those who are receiving high-dose corticosteroids or those with history of fractures, and those who are postmenopausal. The 2009 KDIGO guidelines suggest bone biopsy to guide treatment, especially before bisphosphonate therapy, because of the high incidence of adynamic bone disease.

Gout

Hyperuricemia and gout are common among kidney transplant recipients receiving cyclosporine-based immunosuppression, with a reported prevalence of 30% to 84% and 2% to 28%, respectively. Cyclosporine has been suggested to impair renal excretion of uric acid secondary to decreased GFR as well as increased net uric acid reabsorption by the proximal tubule. Potential contributing risk factors for the development of post-transplantation hyperuricemia and gouty arthritis include pretransplantation hyperuricemia, graft impairment, obesity, and diuretic use. In one retrospective cohort study, cyclosporine was found to have an increased relative risk of new-onset gout compared with tacrolimus (adjusted HR 1.25, 95% CI 1.07-1.47).[43] Purine-rich foods such as meat and seafood and purine-rich alcoholic beverages such as beer have been well described to increase gout risk. Of interest, however, purine-rich vegetables were not found to be associated with increased gout risk.[44]

Management of the acute gouty attack includes topical ice and rest of the inflamed joint. Pharmacologic treatments include colchicine, increased corticosteroid dose, or nonsteroidal anti-inflammatory drugs (NSAIDS). The use of NSAIDS, however, should be avoided in patients with impaired allograft function. Other treatment options have included intra-articular corticosteroids and parenteral adrenocorticotropic hormone (ACTH)—the latter being reserved for patients with multiple medical problems such as allograft impairment, gastrointestinal bleeding, or gouty arthritis refractory to conventional therapy.

Management of chronic gout is directed at lowering uric acid levels. Allopurinol, a xanthine oxidase inhibitor, should be started at a low dose (100 mg to 200 mg/day), particularly in the presence of impaired allograft function, because renal insufficiency predisposes to severe allopurinol toxicity as a result of retention of the metabolite oxypurinol. In allopurinol-allergic patients, febuxostat (a non–purine analogue xanthine oxidase inhibitor) can be used. It is administered as 40 mg or 80 mg daily, and the dosage is not modified in renal failure. Both allopurinol and febuxostat should be used cautiously in patients taking AZA because of the inhibition of AZA metabolism by xanthine oxidase inhibitors (e.g., when used in combination therapy with allopurinol or febuxostat, consider AZA dose reduction by 25% and close monitoring of complete blood counts). Alternatively, AZA-to-MMF conversion therapy may be considered. MMF does not interact with allopurinol or febuxostat).

Recombinant pegylated uricase, which converts uric acid to the more soluble product, allantoin, may be rarely used to rapidly reduce uric acid levels in patients refractory to standard therapy. Whether recombinant pegylated uricase has a role in kidney transplant recipients with refractory gout remains to be explored.

Long-term prophylaxis may include reduction or discontinuation of diuretics, chronic low-dose allopurinol or febuxostat therapy, dietary modification, and consideration of alternative immunosuppressive therapy. A cyclosporine-to-tacrolimus switch has been

reported to result in resolution of severe polyarticular gout refractory to conventional therapy. Small doses of colchicine at 0.6 mg daily may also prevent recurrent gouty attacks. However, colchicine should be used with caution, particularly in patients on statin therapy, because of the increased risk of myopathy.

OUTPATIENT CARE

We recommend that patients be seen two to three times a week for the first 2 weeks after transplantation, twice a week for the next 2 weeks, and weekly for the next month. After the first 2 months, the frequency of outpatient visits depends on the complexity of the patient's early postoperative course. Patients with stable graft function and an uneventful postoperative course can return to work or their regular daily activities 2 to 3 months after transplantation. Laboratory assessment during the first month after transplantation should include serum creatinine and electrolyte values, fasting glucose level, liver enzymes, immunosuppressive drug levels, and complete blood count with platelets. Urinalysis (and, if clinically indicated, urine culture and urine protein-creatinine ratio) should also be performed. After the first post-transplant year, annual follow-up at a transplantation center is generally recommended.

CHAPTER 107

Chronic Allograft Injury

Christian Morath and Martin Zeier

DEFINITIONS AND EPIDEMIOLOGY

The results after kidney transplantation have steadily improved over the last 30 years, with a 1-year overall graft survival rate of about 94% and acute rejection rates within the first year after transplantation of 12%.[1] Loss of an allograft because of acute rejection has become a rare event and predominantly occurs in patients who are presensitized against human leukocyte antigens (HLAs).[2] Today, most allografts are lost because of a phenomenon called *chronic allograft injury.* Every year, about 4% of kidney grafts are lost (Fig. 107-1). Only a decade ago, it was believed that nonimmunologic causes were the main factors leading to chronic allograft injury and graft loss.[3] However, our understanding has changed, and HLA alloantibodies are today believed to be the main culprit, accounting for more than half of graft losses in the long run.[4] With the acknowledgment of alloantibodies as the major factor that contributes to graft failure, the term *chronic allograft nephropathy* has been replaced by more specific terminology in the Banff classification of renal allograft pathology (Box 107-1).[5,6] A frequent pathologic feature of chronic allograft injury is interstitial fibrosis or tubular atrophy (see the later discussion of pathology and Fig. 107-2), but this is a nonspecific finding and does not imply any specific cause for the chronic allograft injury.

Whereas immunologic causes are now believed to be mainly responsible for late allograft injury and graft failure, nonimmunologic causes still represent significant risk factors for (late) graft injury and graft loss. The donor graft itself may present with significant preexisting disease, limiting long-term graft survival.[7] In addition, chronic interstitial fibrosis and tubular atrophy may result from early damage to the allograft such as ischemia-reperfusion injury or early acute rejection. Calcineurin inhibitor (CNI) nephrotoxicity, recurrent glomerular disease, and BK virus (BKV) infection but also chronic interstitial fibrosis and tubular atrophy originating from either hypertension or dyslipidemia further contribute to graft damage and graft loss in the long-run.

Although some allografts are lost as a result of one specific cause, others accumulate the burden from several different causes with gradual loss of functioning nephrons. Main contributors to late graft injury and late graft loss are summarized in Box 107-2.

PATHOGENESIS: NONIMMUNOLOGIC FACTORS

Donor Age, Donor Gender, and Donor-Recipient Size Mismatching

Long-term graft survival is reduced in kidneys from older donors, an effect that is more pronounced in deceased compared with living kidney transplant recipients.[8] Impaired graft survival is attributed to a differential response of the older organ to injury, an impaired capacity to withstand stress, a limited ability to repair structural damage, or amplification of external injury as a result of preexisting structural abnormalities.[9]

Reduced nephron mass resulting in glomerular hyperfiltration and hypertension with accelerated senescence is also a postulated mechanism for a progressive decline in graft function.[10] The effect of kidney size mismatching is thought to be related to insufficient numbers of nephrons within the donor kidney, which in turn leads to compensatory hyperfiltration.[11] Although there are experimental data to support this hypothesis, the extent to which an inadequate number of nephrons contributes to chronic injury in clinical transplantation is unknown.

Female donor gender negatively affects kidney graft survival, with reduced survival when female grafts are transplanted into male recipients (risk ratio 1.22). This is not only a result of reduced nephron mass ("nephron underdosing"), because a comparable effect is found for cardiac allografts. Other mechanisms may include possible differences in the immunogenicity of male and female grafts.[12,13]

Ischemia-Reperfusion Injury and Delayed Graft Function

Graft survival is lower in recipients with longer ischemia times, and longer cold ischemia time represents a risk factor for the development of interstitial fibrosis and tubular atrophy at 6 months after transplantation.[14] Ischemia-reperfusion injury may also trigger immune-mediated injury because ischemia and oxidative injury resulting from reperfusion are associated with upregulation of major histocompatibility complex (MHC) antigens, activation of the adaptive immune response, especially antigen-presenting cells and Toll-like receptors (TLRs), and release of proinflammatory cytokines, which can lead to acute rejection and subsequent interstitial fibrosis and tubular atrophy.[15]

Delayed graft function, commonly defined by the need for dialysis in the first week after transplantation, is a risk factor for interstitial fibrosis and tubular atrophy.[16] There are also independent associations between delayed graft function and late graft failure and between delayed graft function and graft failure that is mediated by acute rejection. Major risk factors for delayed graft function are prolonged cold ischemia time, donor age older than 50 years, and the presence of HLA alloantibodies.[2]

BK Virus Nephropathy

BK virus is an endemic polyomavirus that is usually acquired during childhood and persists in the urinary tract. Although it is asymptomatic in the immunocompetent host, it becomes activated in the immunocompromised patient. Viremia may be found in 10% to 30% of patients within the first 6 months after transplantation, with

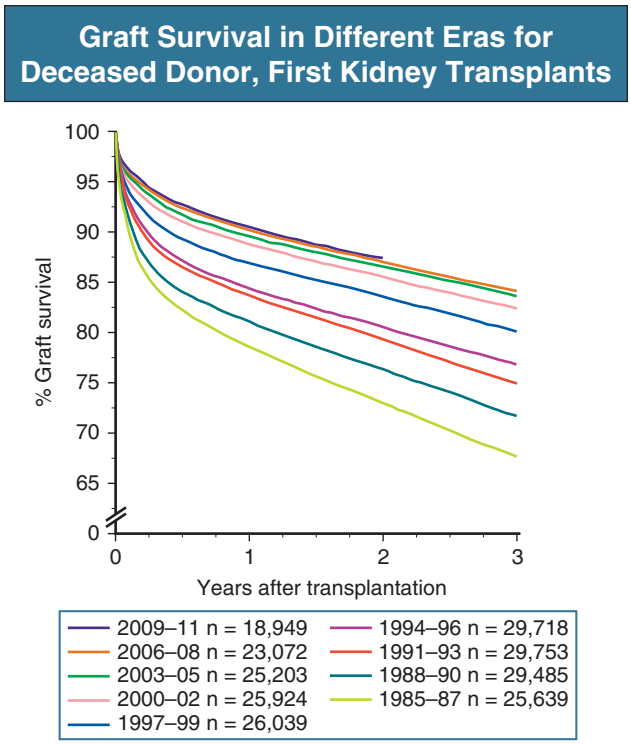

Figure 107-1 Graft survival for recipients of a first deceased donor kidney transplant according to the year of transplantation. Graft survival has steadily improved over the last 25 years because of a reduction in both early and late graft loss. *(With permission from Prof. Gerhard Opelz, CTS Study.)*

Banff Classification of Renal Allograft Pathology

1. Normal

2. Antibody mediated rejection

- Documentation of circulating antidonor antibodies and C4d or allograft pathology
- C4d deposition without morphologic evidence of active rejection (C4d+), presence of circulating antidonor antibodies, no signs of acute or chronic T cell–mediated or antibody-mediated rejection

Acute antibody-mediated rejection

- C4d+, presence of circulating antidonor antibodies, morphologic evidence of acute tissue injury, such as:
  - I. ATN-like minimal inflammation
  - II. Capillary and glomerular inflammation and/or thromboses
  - III. Arterial—v3

Chronic active antibody mediated rejection

- C4d+, presence of circulating antidonor antibodies, morphologic evidence of tissue injury such as:

  Glomerular double contours and/or peritubular capillary basement membrane multilayering and/or interstitial fibrosis–tubular atrophy and/or fibrous intimal thickening

3. Borderline changes

- Suspicious for acute T cell–mediated rejection
- No intimal arteritis but foci or tubulitis (t1, t2, or t3 with i0 or i1)

4. T cell–mediated rejection

Acute T cell–mediated rejection

Type

- IA Interstitial infiltration and moderate tubulitis (i2 or i3 and t2)
- IB Interstitial infiltration and severe tubulitis (i2 or i3 and t3)
- IIA Mild to moderate intimal arteritis (v1)
- IIB Severe intimal arteritis (v2)
- III Transmural arteritis and/or fibrinoid change and/or smooth muscle necrosis

Chronic active T cell–mediated rejection

- Chronic allograft arteriopathy
- Arterial fibrosis with mononuclear cell infiltration in fibrosis

5. Interstitial fibrosis and tubular atrophy, no specific cause (formerly known as *chronic allograft nephropathy* [CAN])

Grade

- I Mild interstitial fibrosis and tubular atrophy (<25% of cortical area)
- II Moderate interstitial fibrosis and tubular atrophy (26% to 50% of cortical area)
- III Severe interstitial fibrosis and tubular atrophy (>50% of cortical area)

6. Changes thought not due to rejection—either acute or chronic

Main Factors Contributing to Late Graft Injury and Late Graft Loss

Donor Factors
- Deceased donor kidney (DBD or DCD)
- Older donor age, female donor
- Donor vascular disease
- Ischemia-reperfusion injury and long ischemia time
- Delayed graft function

Recipient Risks (Nonimmune)
- Obesity
- Urinary tract infection
- Transplant ureteral obstruction
- BK virus nephropathy
- Calcineurin inhibitor toxicity
- Recurrent renal disease or *de novo* glomerulonephritis
- Hypertension, dyslipidemia, smoking
- Diabetes (preexisting or post-transplantation)

Recipient Risks (Alloimmune)
- Child or adolescent recipient, ethnicity
- Variable medication trough concentrations from malabsorption or nonadherence
- HLA mismatches, presensitization status (donor-specific HLA alloantibodies)
- Acute rejection that is severe, corticosteroid resistant, vascular, antibody mediated, or late occurring
- Late *de novo* donor-specific antibodies and chronic (antibody-mediated) rejection

Box 107-2 Main factors contributing to late graft injury and late graft loss. *DBD,* Donation after brain death; *DCD,* donation after cardiac death; *HLA,* human leukocyte antigen. *(Modified from reference 57.)*

biopsy-proven BKV-associated nephropathy in 1% to 10% of patients. BKV-associated nephropathy mimics the pattern of interstitial cellular rejection but may be distinguished in immunohistochemistry by a positive staining for the SV40 antigen. BKV-associated nephropathy, if untreated, may lead to severe interstitial fibrosis and tubular atrophy and graft loss in the majority of patients. The mainstay of therapy is the reduction of immunosuppression.[17] The diagnosis and management of BKV nephropathy are discussed further in Chapter 105.

Calcineurin Inhibitor Toxicity

Calcineurin inhibitor nephrotoxicity affects all histologic compartments of the transplanted kidney. Characteristic chronic CNI lesions include medial arteriolar hyalinosis, striped interstitial fibrosis, global glomerulosclerosis, and tubular microcalcification unrelated to other causes, such as tubular necrosis and hyperparathyroidism.[18,19] CNI-induced arteriolopathy is characterized by nodular hyaline deposits in the media of afferent arterioles sufficient to cause narrowing of the vascular lumen.[20,21] It is attributed to eosinophilic transformation and vacuolization of smooth muscle cells with subsequent necrosis. Arteriolar hyalinosis is the most reliable diagnostic marker of CNI nephrotoxicity. Confirmation of the diagnosis is made by exclusion of other causes, such as donor hyalinosis (which can be detected on the implantation biopsy specimen), diabetes, and hypertensive nephrosclerosis. Striped fibrosis is subjectively defined by a dense stripe of cortical fibrosis and atrophic tubules adjacent to normal cortex and is traditionally regarded as pathognomonic of CNI nephrotoxicity, but its appearance can be seen in any cause of fibrosis, especially if it is a result of microvascular injury. It is likely that the associated arteriolopathy and narrowing of the lumen contribute to development of fibrosis and atrophy after watershed infarcts within areas of ischemia. Local hypoxia leads to formation of free oxygen radicals, which promote cellular death by apoptosis. In addition, upregulation of transforming growth factor β (TGF-β) is considered an important etiologic factor in CNI toxicity.[19]

Calcineurin inhibitor toxicity was long believed to be the major factor contributing to late allograft loss. However, there has been a shift in this paradigm, and today CNI nephrotoxicity is believed to be responsible for only a smaller proportion of graft failures. The Long-Term Deterioration of Kidney Allograft Function (DeKAF) study demonstrated that 70% of patients with a primary or secondary histologic diagnosis of CNI nephrotoxicity had evidence of deposition of the complement split-product C4d and had donor-specific antibodies (DSAs) linking chronic graft failure to alloimmunity rather than CNI nephrotoxicity.[22,23]

Recurrent and *De Novo* Glomerular Diseases

Recurrent glomerulonephritis (GN) is diagnosed by exclusion of donor-transmitted disease and *de novo* GN. Its relative importance for graft loss increases as graft survival lengthens.[24] Given that it is a relatively common occurrence and has implications for treatment and retransplantation, recurrent GN should be looked for carefully in patients with a prior diagnosis of GN. Diagnosis and management of recurrent disease are discussed further in Chapter 108.

Cardiovascular Risk Factors

The vasculopathy in chronic allograft injury resembles systemic vascular disease, raising the possibility that conventional risk factors for cardiovascular disease may be implicated. Hypertension occurs in about 70% to 90% of transplant recipients. In a multicenter, retrospective study of 29,751 kidney transplant recipients, elevated systolic blood pressure above 180 mm Hg (compared with <140 mm Hg) at 1 year was associated with a doubled risk of graft failure at 7 years.[25] Hypertension in these patients may be related to pretransplant hypertension, vascular disease, corticosteroid therapy, CNI therapy, or graft dysfunction.

Dyslipidemias, including raised levels of total cholesterol, low-density lipoprotein cholesterol, and triglycerides, and cigarette smoking have also been associated with late graft failure. Some studies also suggest that hyperuricemia, which is common in patients with metabolic syndrome, may have a role in chronic allograft injury.

The management of hypertension, dyslipidemia, and other cardiovascular risk factors in the transplant recipient is discussed further in Chapter 106.

PATHOGENESIS: IMMUNOLOGIC FACTORS

Acute Rejection

Acute cellular rejection, vascular or corticosteroid-resistant rejection, subclinical rejection, and late acute rejection all contribute to the burden of chronic allograft injury. Early acute cellular rejection (within 3 months of transplantation) that is adequately diagnosed and treated and in which the serum creatinine returns to baseline values after treatment usually has no impact on long-term graft survival. But late acute rejection and rejection in which serum

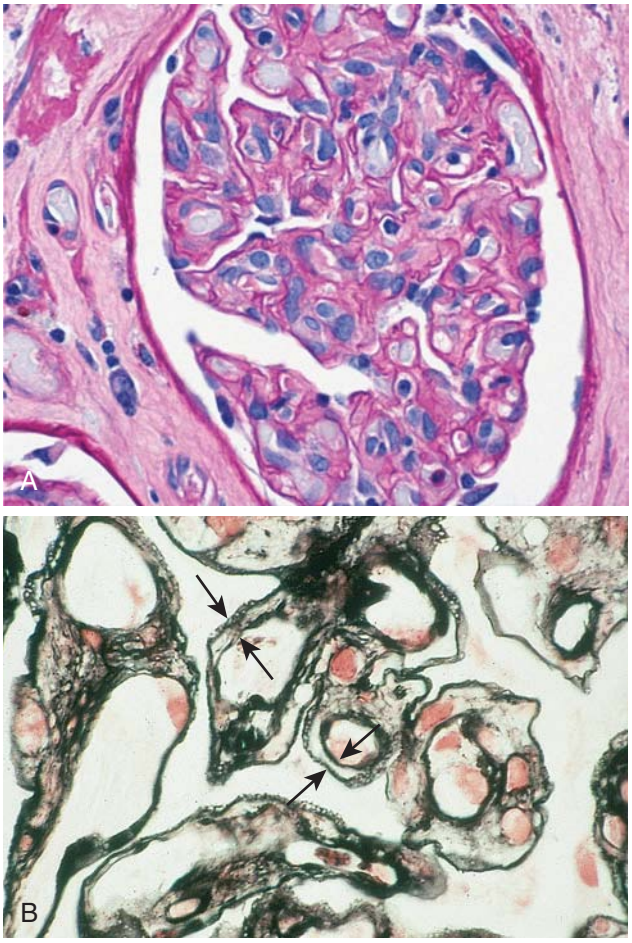

Figure 107-3 Transplant glomerulopathy: light microscopy. A, Note the mesangial expansion and thickening of the glomerular basement membrane (GBM). **B,** Note the GBM reduplication in capillary loops *(between arrows).*

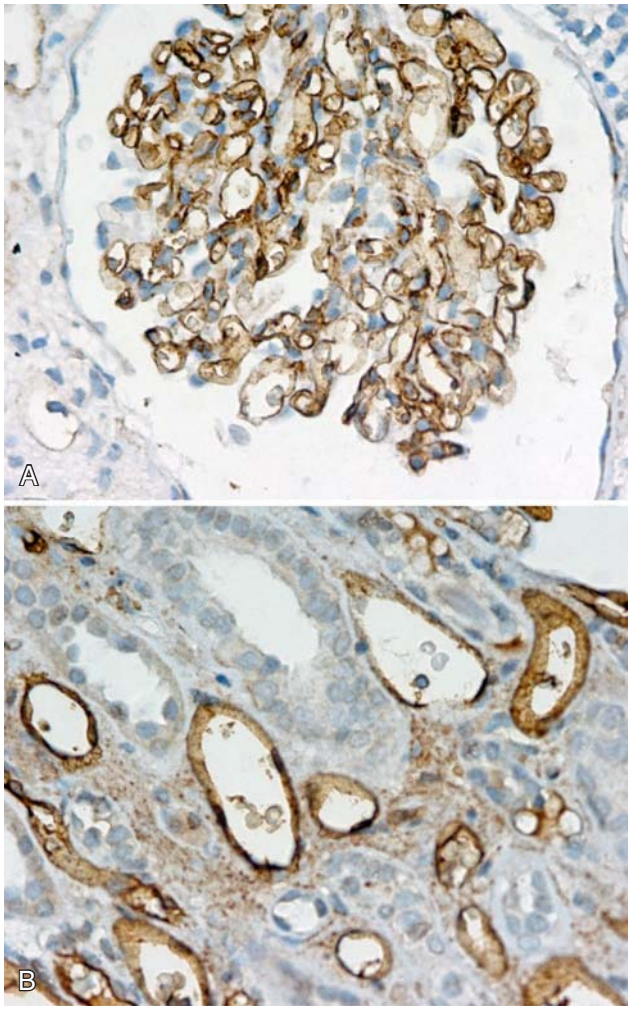

Figure 107-4 C4d immunoperoxidase staining in association with chronic antibody-mediated rejection. Staining of glomerular capillaries **(A)** and circumferential staining of peritubular capillaries **(B)** are typical.

creatinine does not return to baseline usually translates into interstitial fibrosis and tubular atrophy and/or vascular damage, contributing to graft injury. Multiple and severe late acute cellular rejection episodes are predictive of chronic graft dysfunction more than early cellular rejection and acute vascular rejection, which have stronger associations with acute graft loss.[26] There is some evidence from protocol biopsy studies that subclinical cellular rejection may also be an important factor contributing to chronic graft injury, although there is no consensus on this point.[27,28]

In addition to the direct effects of cellular rejection on graft function, acute cellular rejection may be linked to the development of DSA and subsequent antibody-mediated rejection.[29]

Chronic Antibody-Mediated Rejection

Chronic antibody-mediated rejection is one of the leading causes of graft loss, together with death with a functioning graft, recurrent renal disease, and interstitial fibrosis and tubular atrophy of unknown origin.[30]

For the diagnosis of antibody-mediated kidney graft rejection, histologic features of antibody-mediated rejection in the biopsy (Figs. 107-3 to 107-5), together with positivity for the complement split product C4d in peritubular capillaries (see Fig. 107-4) and/or the detection of circulating DSAs, are required. Especially in chronic antibody-mediated rejection, however, C4d in peritubular capillaries may be negative (C4d-negative antibody-mediated rejection).[6] C4d-negative antibody-mediated rejection shares the same histologic and ultrastructural features as C4d-positive rejection. Exact criteria for the definition of C4d-negative antibody-mediated rejection are currently lacking; however, it is believed that more than 50% of all chronic antibody-mediated rejection episodes are C4d negative.

Unrecognized DSAs, if strongly reactive and complement activating, can cause hyperacute rejection or accelerated antibody-mediated rejection in the early phase after kidney transplantation. Acute antibody-mediated rejection in the early phase occurs in about 1% to 6% of patients; however, this number may increase up to 21% to 55% in patients who had detectable DSAs already before transplantation and who received desensitization therapy.[31-33] Weakly positive DSAs have been associated with rather subtle types of graft damage, often leading to delayed graft function.[2] Early damage can later translate into chronic rejection, most probably because the structure of the endothelium is no longer intact and new antigenic epitopes are expressed on the surface of transplanted tissue. During later phases after transplantation, insufficient immunosuppression can facilitate the development of *de novo* DSAs against these new epitopes and result in chronic antibody-mediated rejection and failure of the transplanted organ. *De novo* DSAs but also persistence or re-emergence of DSAs that were detectable before transplantation are associated with poor allograft outcome.

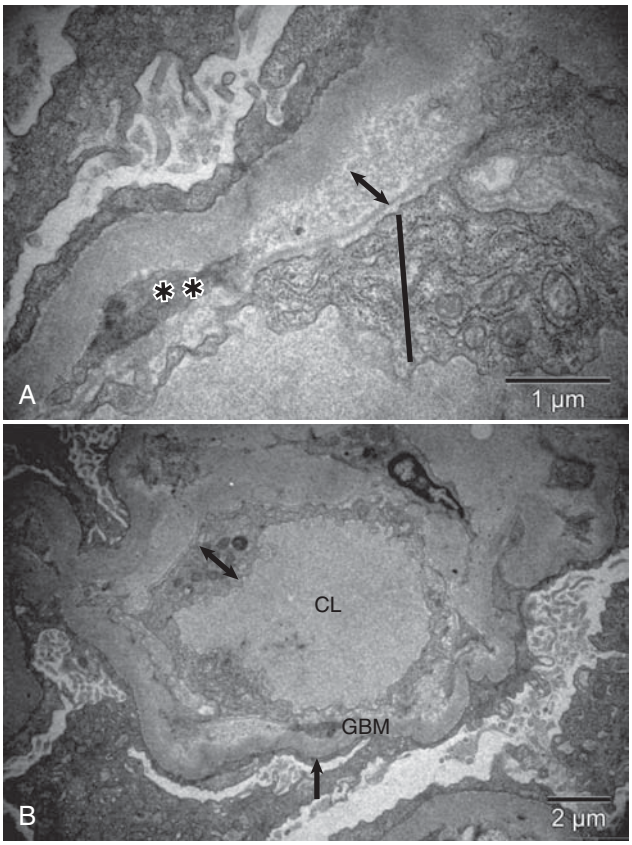

Figure 107-5 Transplant glomerulopathy: electron microscopy. A, Section of a glomerular capillary loop (×24,000) demonstrating mesangial interposition *(asterisks),* subendothelial expansion and new lamina densa *(double arrow),* and endothelial hypertrophy *(line).* **B,** A complete glomerular capillary loop *(CL)* with glomerular basement membrane (GBM) thickening *(single arrow),* endothelial hypertrophy *(double arrow),* expanded subendothelial space, and new lamina densa *(single arrow).* Apparent GBM duplication is a result of mesangial interposition and formation of new lamina densa.

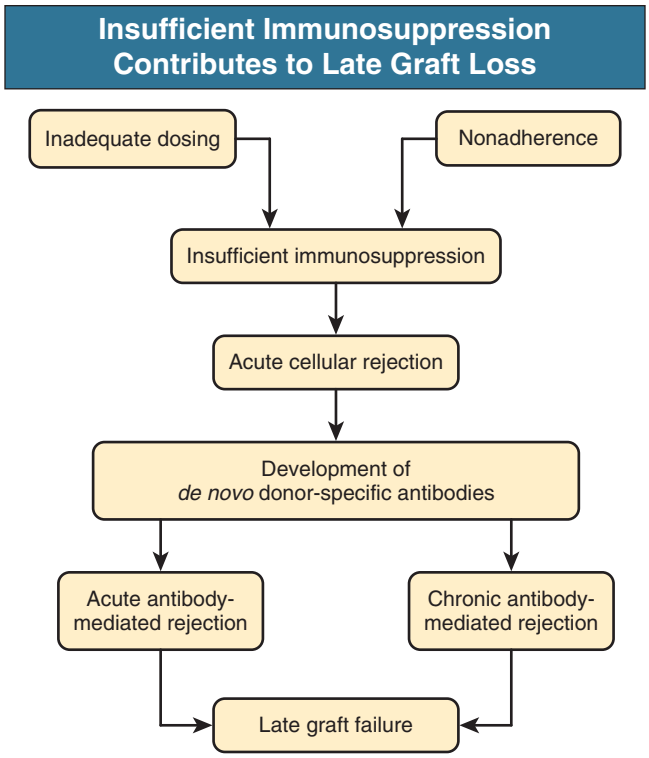

Figure 107-6 Insufficient immunosuppression contributes to late graft loss. *HLA,* Human leukocyte antigen.

Chronic antibody-mediated rejection is found more frequently in patients who are nonadherent to immunosuppressive medication or in whom immunosuppression was reduced for other reasons—for example, because of recurrent infection or malignancy or planned conversion to CNI-free or corticosteroid-free immunosuppressive protocols.[34-36] Additional risk factors for the development of *de novo* DSAs and antibody-mediated rejection are HLA class II DR mismatches between donor and recipient, prior cellular rejection episodes, and younger recipient age. In many patients with late antibody-mediated graft loss, even when HLA class I alloantibodies are detectable, HLA class II *de novo* DSAs are considered to be mainly responsible for rejection. In a recent study on the evolution of HLA alloantibodies after transplantation, *de novo* DSAs appeared at a mean of 4.6 years after transplantation, and the prevalence of *de novo* DSAs after 10 years was 20% in those adherent to the immunosuppressive regimen, as compared with 60% in nonadherent graft recipients.[36] In another study, DSAs were found in 37% of patients who had an indication biopsy 7 days to 31 years after transplant.[4] Especially *de novo* DSAs, which made up 60% of all DSAs, that were directed against HLA class II antigens were associated with strongly impaired graft survival.

Other antibodies that are discussed in the evolution of chronic antibody-mediated rejection are MHC class I–related chain A (MICA) antibodies, angiotensin II type 1 receptor-activating antibodies, and other antiendothelial cell antibodies.[37,38] The exact impact of these antibodies on the outcome of kidney and other organ transplants is yet to be determined.

Insufficient Immunosuppression and Nonadherence to Medication

The recognition that HLA alloantibodies are responsible for a great proportion of late graft losses[38,39] has focused attention on the role of insufficient immunosuppression and nonadherence to immunosuppressive medication as significant factors in chronic graft loss (Fig. 107-6).[34,40]

A retrospective analysis of more than 25,000 kidney transplant recipients showed that reduction or discontinuation of cyclosporine, tacrolimus, or mycophenolate mofetil after the first post-transplant year in patients with good graft function was associated with significantly reduced subsequent kidney graft survival.[34] In a recent study in which 64% of graft losses in a cohort with indication biopsies were attributable to (antibody-mediated) rejection, about half of the patients with rejection-associated loss of the allograft were identified as nonadherent.[40]

Patients at high risk for nonadherence are young adults who are in the transition phase from pediatric to adult nephrology care. Other risk factors are previous nonadherence, psychiatric disorders, substance abuse, and insufficient socioeconomic support, and also adverse effects from immunosuppressive medication. Insufficient immunosuppression may also occur during immunosuppressive minimization (tapering) or CNI avoidance trials. In a recent study, 14 out of 61 patients (23%) who were converted from cyclosporine to everolimus at 3 to 4.5 months after transplantation developed DSAs, compared with only 7 out of 65 patients (11%) who continued on cyclosporine.[35] Eight patients on everolimus but only two patients on cyclosporine developed antibody-mediated rejection. Therefore

these patient cohorts should be screened rigorously for the development of alloantibodies and antibody-mediated allograft injury.

CLINICAL MANIFESTATIONS

Routine laboratory evaluation of graft function does not facilitate the early diagnosis of chronic allograft injury. A rise in serum creatinine is a late marker of graft dysfunction. The reduction in the glomerular filtration rate (GFR) is usually estimated by equations such as the Modification of Diet in Renal Disease (MDRD) formula, the Nankivell formula, or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula. However, substantial nephron loss may occur before a rise in serum creatinine becomes evident.

Persistent or worsening proteinuria is also a late sign of chronic allograft injury. Proteinuria may be assessed by dipstick urine analysis, by spot urine protein-creatinine ratio, or by measurement of the 24-hour urine protein excretion. Proteinuria exceeding 1 g/day or in the nephrotic range may predominantly occur with recurrent or *de novo* GN or with severe chronic antibody-mediated changes such as transplant glomerulopathy (see Figs. 107-3 to 107-5). A definite diagnosis of the allograft pathology may be achieved only by a transplant biopsy together with the serologic testing for alloantibodies, and the exclusion of viral disease such as BKV or cytomegalovirus (CMV).

PATHOLOGY

Chronic interstitial fibrosis and tubular atrophy, which may be accompanied by vascular changes and glomerulosclerosis (see Fig. 107-2), represent the final pathway of nephron injury and are not specific for any graft disease. Interstitial fibrosis and tubular atrophy are found in most late graft biopsies, whether from early graft damage (such as tubular injury from ischemia-reperfusion injury, overt or subclinical rejection, or even preexisting disease of the donor) or later graft damage (from CNI toxicity, hypertension and hyperlipidemia, recurrent glomerular disease, or immune-mediated injury) or of unknown origin.

Chronic antibody-mediated rejection is characterized by structural remodeling of the glomerular basement membrane (GBM; so-called *transplant glomerulopathy*) and similar changes in the peritubular capillaries together with interstitial fibrosis and tubular atrophy and fibrous thickening of arteries (see Figs. 107-3 to 107-5). Transplant glomerulopathy is characterized by duplication of glomerular capillary basement membranes and mesangial matrix expansion, in the absence of immune deposits. In addition, there may be (but not necessarily) a deposition of C4d in glomerular capillaries, and also in peritubular capillaries (see Fig. 107-4). Clinicopathologic studies suggest that transplant glomerulopathy is a manifestation of capillary injury occurring in conjunction with interstitial, peritubular capillary, and glomerular inflammation, although it may also occur independently of interstitial fibrosis and tubular atrophy, or transplant arteriopathy.[41] On electron microscopy, there is expansion of the subendothelial space with deposition of flocculent or fibrillary material, interposition of mesangial cell cytoplasm in the lamina densa, and mesangial matrix expansion (see Fig. 107-5). Ultrastructural abnormalities characteristic of endothelial activation occur long before GBM duplication and graft dysfunction are evident, implying that endothelial injury is the initial insult that resulted in GBM remodeling.[42] An association between transplant glomerulopathy and peritubular capillary basement membrane duplication has been well described, suggesting that the process resulting in transplant glomerulopathy involves the entire glomerular and peritubular capillary beds.[43,44]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When chronic allograft injury has been identified by a gradual rise in serum creatinine with or without proteinuria, ultrasound should be performed to exclude ureteral or vascular problems and to assess the Doppler resistive index. The Doppler resistive index gives an estimate of intrarenal (but also systemic) compliance and is most useful in longitudinal studies in the same patient to assess progressive graft vascular injury.

Screening for BKV in serum or urine is also advised for all kidney transplant recipients at 3-month intervals during the first two years after transplantation. Circulating HLA alloantibodies should also be documented and may further guide diagnostics and therapy. Many centers now perform routine HLA alloantibody screening in stable graft recipients at different time points after transplantation to facilitate early diagnosis of antibody-mediated rejection. Although there is consensus that HLA alloantibodies are responsible for a significant proportion of late graft losses and that HLA antibodies in the context of deteriorating graft function are harmful, the significance of HLA alloantibodies that are detected solely during routine screening remains uncertain.[45,46]

Allograft biopsy is required to document the presence of interstitial fibrosis and/or transplant glomerulopathy and to look for other treatable causes of chronic allograft injury (see Box 107-1). The role of protocol biopsies in the early detection of chronic allograft injury remains controversial.

Because the etiology of chronic allograft dysfunction is multifactorial, any specific diagnosis is made by combination of a biopsy with a review of the patient's past history to identify important etiologic factors, such as preexisting donor disease, prior rejection, and high-titer anti-HLA antibodies, as well as issues not related to alloimmunity, such as CNI nephrotoxicity, *de novo* GN, or recurrent renal disease. Chronic allograft dysfunction is common and can have many causes; however, if it is left untreated, it can ultimately result in progressive renal injury, which in turn will heal by scarring and interstitial fibrosis. An overview of the differential diagnosis of chronic allograft dysfunction is given in Box 107-2.

MANAGEMENT

Prevention of Antibody-Mediated Allograft Injury

Prevention of antibody-mediated allograft injury should be initiated early, indeed before transplantation. Preventive measures include avoidance of sensitization by limitation of blood transfusions and poor HLA matching in previous transplants.[47,48] The introduction of erythropoietin (EPO) about 20 years ago led to a dramatic decrease of recipient sensitization by a significant reduction in blood transfusions.[48] Sensitization should especially be avoided in young patients who may require retransplantation during their lifetime. New measures, such as matching for antibody epitopes in addition to whole HLA alleles, may further help prevent sensitization.

When the patient is already sensitized, antibody-mediated allograft injury can best be prevented by transplantation of the patient with an organ against which the recipient has not developed HLA alloantibodies. This may be achieved by inclusion of patients in special programs such as the Eurotransplant Acceptable Mismatch (AM) Program or by kidney-paired donation.[49,50] However, most

Strategies for the Prevention of Chronic Allograft Injury

- Avoid sensitization in future organ recipients (e.g., avoid blood transfusions, avoid poor HLA matching during first transplantation).
- Obtain complete donor and recipient typing and precise knowledge on HLA alloantibodies at time of transplantation.
- Minimize ischemia-reperfusion injury (e.g., short cold ischemia time).
- Avoid insufficient immunosuppression.
- Perform prophylaxis for CMV (first 3 to 6 months).
- Screen for BKV after transplantation.
- Monitor donor-specific HLA alloantibodies after transplantation (at least in presensitized patients or during drug minimization).
- Perform protocol biopsies to detect subclinical rejection (at least in presensitized patients or during drug minimization).
- Review for nonadherence.

Box 107-3 Strategies for the prevention of chronic allograft injury. *BKV,* BK virus; *CMV,* cytomegalovirus; *HLA,* human leukocyte antigen.

Treatment of Chronic Allograft Injury

Nonimmune

- Treat hypertension (consider ACE inhibitors or ARBs) (see Chapter 106).
- Perform lifestyle modification (stop smoking, control lipids).
- Control diabetes.
- Prevent and treat urinary tract infection (see Chapter 105).
- Target CNI toxicity by reducing or replacing CNI (be aware of risk for insufficient immunosuppression).
- Treat BK virus nephropathy by reducing immunosuppression with or without antiviral therapy (see Chapter 105).

Allloimmune (see Chapter 104)

- Diagnose and treat early acute cellular rejection with corticosteroids or antithymocyte globulin.
- Diagnose and treat acute antibody-mediated rejection by means such as plasma exchange, or immunoadsorption with or without anti-CD20 therapy.
- Diagnose and treat chronic antibody-mediated rejection by means such as intravenous immunoglobulins with or without anti-CD20 therapy.

Box 107-4 Treatment of chronic allograft injury. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNI,* calcineurin inhibitor.

patients with preexisting HLA alloantibodies need desensitization in combination with other measures, to undergo successful transplantation (see Chapter 104).[51]

After transplantation, according to our current knowledge, chronic antibody-mediated rejection is best prevented by the use of conventional triple-drug therapy including CNI, an antiproliferative agent (preferably mycophenolic acid based), and corticosteroids. Induction therapy, with an interleukin-2 receptor antagonist or antithymocyte globulin, should be used to prevent early acute cellular rejection.

Unless a patient is prone to tolerance, insufficient immunosuppression and nonadherence may lead to cellular rejection and then, via development of *de novo* DSAs, to antibody-mediated rejection and graft loss. Precise knowledge of the patient's alloantibody status before and after transplantation is a prerequisite for early diagnosis of allograft injury and early and targeted treatment to prevent antibody-mediated rejection and ensure long-term graft survival. Although it is currently a matter of debate whether alloantibodies should be monitored routinely in all patients who have undergone transplantation, it seems to be justified in immunologically high-risk patients, desensitized patients, and patients with suspected rejection and during therapy for antibody-mediated rejection, with the goal of recognizing allograft injury in its early stages and preventing its progression to chronic rejection. Additional patient groups that may benefit from HLA alloantibody monitoring are those patients undergoing reduction, withdrawal, or change of immunosuppressive drugs, especially in the context of CNI- or corticosteroid-free regimens. Protocol biopsies may further help in guiding post-transplant therapy at least in high-risk recipients, although definitive proof of the usefulness of protocol biopsies is currently lacking.

Strategies for the prevention of chronic allograft injury are summarized in Box 107-3.

Treatment of Chronic Allograft Injury

In all patients with chronic allograft injury, there must be a focus on the effective management of nonimmunologic risk factors for progressive graft failure.

Although reduction of blood pressure to a target below 130/80 is believed to be beneficial, the preferred agent for blood pressure reduction remains controversial; in particular, the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) has not uniformly shown benefit.[52,53] Nor have there been specific studies confirming the benefits of reducing proteinuria in chronic allograft injury, although by extrapolation for other progressive proteinuric diseases (see Chapter 80), there is strong *a priori* evidence for the benefits of reducing proteinuria by renin-angiotensin system (RAS) blockade with dietary salt restriction.

A beneficial effect of treating dyslipidemia with statins in the transplant recipient also remains controversial,[54-56] and the adverse effects of statins such as rhabdomyolysis when used with CNIs must be considered. The management of hypertension, dyslipidemia, and other cardiovascular risk factors in the transplant recipient is discussed in Chapter 106.

After a specific diagnosis has been established, targeted treatments can be initiated. These are discussed further in other chapters and summarized in Box 107-4.

CHAPTER 108

Recurrent Disease in Kidney Transplantation

Steven J. Chadban and Tony Kwan

Kidney transplantation is a treatment, not a cure. Although transplantation may restore kidney function, it does not necessarily remove the cause of the original kidney disease. Glomerulonephritis (GN) and diabetes are the two leading causes of end-stage renal disease (ESRD) worldwide and are the primary underlying diseases of patients undergoing kidney transplantation, and both diseases may recur.

The longer that a transplant remains *in situ,* the more likely it is to be affected by recurrence. As graft survival rates have increased over the past 30 years, mostly because of more effective antirejection therapies that prevent early graft loss, the apparent incidence of recurrence has grown.[1] An analysis of U.S. Renal Allograft Disease Registry data examining GN recurrence demonstrated a prevalence of 2.8% at 2 years, 9.8% at 5 years, and 18.5% at 8 years of follow-up after transplantation, and such patients were twice as likely to experience graft failure compared with those without recurrence.[2]

Recurrence has a powerful impact on transplant survival and one that is increasingly apparent with time after transplantation. In an analysis of data from the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) including more than 1500 patients with biopsy-proven GN who received a kidney transplant, biopsy-proven recurrence was found to cause graft loss in 0.5% within 1 year after transplantation, 3.7% within 5 years, and 8.4% within 10 years after transplantation[3] (Fig. 108-1). This study and several others have found recurrent disease to be the third most common cause of graft failure beyond the first year after transplantation, behind death with a functioning graft and chronic allograft nephropathy (CAN), but substantially ahead of acute rejection[3] (see Fig. 108-1).

De novo GN and new-onset diabetes after transplantation (NODAT) may also affect the transplanted kidney, although both are relatively uncommon. Both conditions may be difficult to distinguish from recurrence or from CAN. Like recurrent disease, the prevalence of both appears to increase with time after transplantation. Given the high incidence of NODAT coupled with general increases in graft survival,[4] it is possible that *de novo* diabetic nephropathy in particular may become a significant clinical problem in the future. However, present data suggest that the major impact of NODAT in the first 10 years after transplantation is an increase in cardiovascular mortality with little impact on death-censored graft failure.[5]

DEFINITIONS

Diagnosis of recurrence requires histologic demonstration of the same disease involving both the native and transplanted kidneys. Diagnosis of recurrence causing graft failure requires a clinical decision that recurrence was the dominant contributor to graft loss (other contributors, such as CAN, may be present). A histologic diagnosis of the primary kidney disease is not obtained for all patients with ESRD, and the majority of transplant recipients do not undergo biopsy to look specifically for recurrent disease (which may require immunohistologic and electron microscopic examination of the biopsy specimen).[1] Coupled with the tendency of clinicians to make a clinical diagnosis of CAN and thereby avoid biopsy in patients with declining graft function and proteinuria, the true incidence of disease recurrence is not known and is likely underestimated in existing literature.

Additional factors confound the available evidence. Many reports of disease recurrence are retrospective, single-center studies. Recall bias and incomplete documentation, changes in practice over time, and peculiarities of local patient populations and local practices may limit relevance to other populations. The most definitive reports have come from analyses of the large registry databases of Europe, the United States, and Australasia. Registries capture data on large numbers of patients but are subject to bias because of factors including unit participation rates; quantity and type of data collected; accuracy, uniformity, and consistency of reporting by units; and reliability of data entry. How recurrence is defined and diagnosed and which outcomes are measured is crucial. For example, IgA nephropathy (IgAN) recurred in 58% of patients in one series in which all recipients underwent biopsy,[6] but in approximately 25% of cases in which biopsy was performed only when clinically indicated.[7] When graft loss from IgAN recurrence is the outcome measure, the risk decreased to approximately 10% at 10 years of follow-up.[3] Thus, definition of recurrence, outcome measures, study design, era, and source of data all need to be considered in assessing the published literature.

RECURRENT GLOMERULONEPHRITIS

Virtually all GN may recur after transplantation; however, the rate and consequences of recurrence vary enormously. For example, anti–glomerular basement membrane (GBM) disease (Goodpasture disease) recurs only rarely, but when it does, it is likely to cause rapid graft loss. In contrast, dense deposit disease (DDD; formerly known as type II membranoproliferative *glomerulonephritis* [MPGN]) recurs in more than 80% of patients; however, the disease tends to be very slowly progressive, and graft survival beyond 10 years is typical. Numerically, recurrence of focal segmental glomerulosclerosis (FSGS), IgAN, and membranous nephropathy (MN) are the most frequently encountered clinical problems (Fig. 108-2).

Several factors may influence the risk of recurrence in addition to the underlying type of GN. Time of follow-up is clearly important and may be related to the duration of exposure of the graft to the nephritogenic factors responsible for GN.[1] In general, grafts that are lost early because of rejection are exposed relatively briefly and rarely develop recurrence. In contrast, those grafts that survive long term are exposed to nephritogenic factors for longer and are more likely to develop recurrent GN. Consistent with this concept, recipients of human leukocyte antigen (HLA)–identical transplants rarely suffer

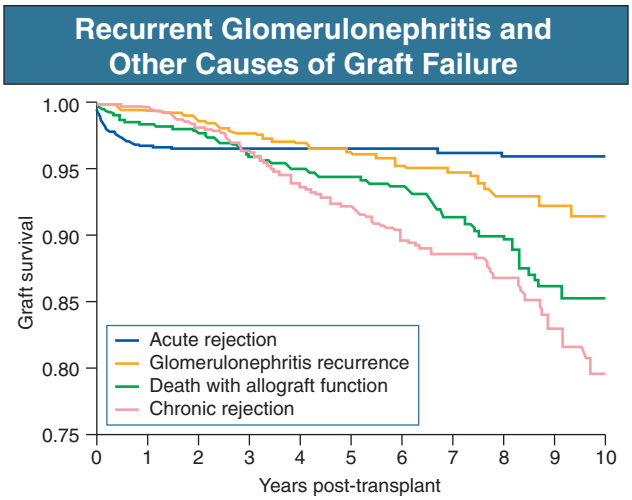

Figure 108-1 Recurrent glomerulonephritis and other causes of graft failure. Kaplan-Meier analysis of the relative contributions of acute rejection, glomerulonephritis recurrence, death, and chronic allograft nephropathy to graft loss during the first 10 years post-transplantation among patients who underwent transplantation because of end-stage renal disease caused by glomerulonephritis. *(Modified from reference 3.)*

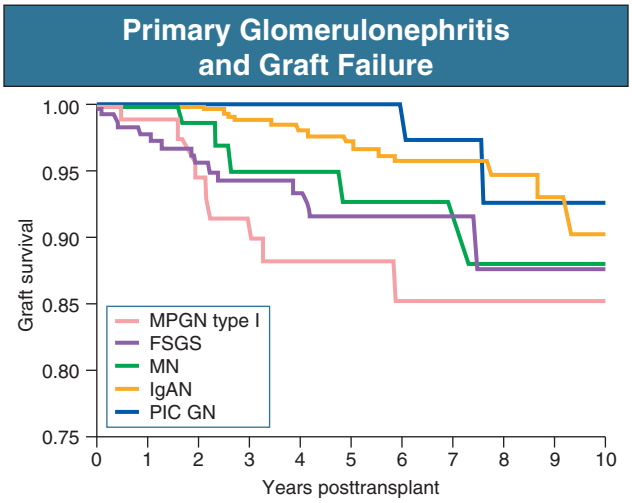

Figure 108-2 Primary glomerulonephritis and graft failure. rejection and enjoy prolonged graft survival but have a high rate of recurrent GN.[8] In one report of HLA-identical recipients, recurrent GN was present in 36% to 42% of those in whom biopsy was performed and resulted in 24% of graft losses, being the second most frequent cause of graft loss after death in this group.[8] Patients sustaining first graft loss from recurrent GN are also at higher risk of recurrence in a subsequent graft.

The type of immunosuppressive agents may be significant; however, data in this area are sparse. Given that immune mechanisms contribute to the pathogenesis of most types of GN and that immunosuppression is effective in the treatment of several types, it is logical that immunosuppression should decrease the incidence and severity of recurrence after transplantation. Improvements in immunosuppression over the past 40 years have led to reduced rates of acute rejection. Such improvements may also have also had an impact on rates of graft loss from GN recurrence, which have declined by nearly 50% over the past 10 years according to one ANZDATA registry analysis.[9]

United States Renal Data System (USRDS) registry data failed to demonstrate superiority of any individual immunosuppressive agent over others on the incidence of recurrence.[10] Nevertheless, there are reports that suggest the immunosuppressive regimen may be important. For example, one small retrospective study found that induction therapy with rabbit antithymocyte globulin was associated with a lower risk of IgAN recurrence compared with either anti-CD25 antibodies or no induction.[11] Corticosteroid withdrawal may also lead to increased rates of recurrence,[12] especially in patients with underlying IgAN, in whom a twofold increase in the risk of graft failure from recurrence of IgAN has been reported.[9] Similarly, inclusion or addition of cyclophosphamide to immunosuppressive regimens may be helpful in the treatment of recurrent vasculitis affecting the graft.[13] The use of sirolimus may also result in proteinuria and renal dysfunction, especially in patients with an underlying GN, suggesting that sirolimus may accelerate glomerular injury in the graft.[14] Effects of individual agents are likely to be disease specific, and much needs to be learned in this area.

Strategies to reduce the risk of recurrence have been reported. Bilateral native nephrectomy as a means of eliminating persistent antigenic stimulation appears unhelpful; indeed, nephrectomized patients experienced a higher incidence of recurrence compared with those with native kidneys left *in situ* in one large single-center, retrospective study.[15] Induction of disease remission before transplantation and prolonged time on dialysis pretransplantation, both aimed at permitting disease "burnout," do not appear to be effective except in the case of anti-GBM disease, in which a delay in transplantation until the patient has been serologically negative for at least 6 months virtually eliminates the risk of recurrence.[3] Avoidance of living related donation has been debated for years but overall appears not to have any impact on risk of recurrence.[16]

As with GN in native kidneys, proteinuria, hematuria, and deterioration in kidney function are the cardinal manifestations of recurrent GN. The pattern of renal and extrarenal manifestations is frequently similar to that of the native disease, except that, in our opinion, the rate of progression may in general be slower. Extrarenal features of the primary condition may recur, such as thrombocytopenia and hemolysis in hemolytic uremic syndrome (HUS) and extrarenal vasculitis in recurrent antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis. Serology may be helpful in some patients, such as anti-GBM antibody detection in those with Goodpasture disease, but may be inconsistent in others, such as those with recurrent lupus nephritis (LN).

The differential diagnosis of recurrent GN is clinically important because management may vary according to the diagnosis (Table 108-1). CAN and diabetic nephropathy, recurrent or *de novo,* may both present with progressive graft dysfunction, proteinuria, and hypertension and may therefore be clinically indistinguishable from recurrence. *De novo* GN should also be considered. Viral diseases of the kidney, particularly BK nephropathy, are an important alternative to consider because a reduction in immunosuppression and specific antiviral therapy may provide benefit. The need to exclude obstructive uropathy and tumors involving the graft warrants an ultrasound scan. Finally, recurrence may coexist with CAN or calcineurin inhibitor toxicity. Indeed, every condition that can lead to chronic graft dysfunction should be considered in the differential diagnosis of recurrence (see Table 108-1 and Chapter 107).

Differential Diagnosis of Recurrent Glomerulonephritis

Diagnosis	Frequency and Timing	Clinical Features	Lab Features	Biopsy Features	Management
Recurrent glomerulonephritis	Common; variable timing, days to years	Proteinuria, hematuria, renal impairment, hypertension	Similar to primary glomerulonephritis; serology may be negative	Same as primary glomerulonephritis[4,5]	Disease specific
De novo glomerulonephritis	Uncommon; variable timing but typically later than recurrence	Proteinuria, hematuria, renal impairment	Type specific	Type specific[4,5,8]	Antiprogression strategies (see Chapter 73)
Chronic allograft nephropathy	Very common; increasing incidence with time	Hypertension, proteinuria, renal impairment Calcineurin inhibitor exposure		Tubulointerstitial fibrosis, arteriolar hyalinosis, transplant glomerulopathy	Minimize calcineurin inhibitor and antiprogression strategies (see Chapter 73)
Graft pyelonephritis	Uncommon Typically early after transplantation	Fever, pyuria, renal impairment	Positive blood or urine cultures	Neutrophil infiltration	Antibiotics
BK nephropathy	Uncommon; typically 1-5 yr after transplantation	Renal impairment, decoy cells in urine	Serum BK PCR positive	Tubulitis with tubular cell atypia and inclusions, normal glomeruli	Minimize immunosuppression and consider antiviral drugs
Acute rejection	Common; early	Renal impairment, oliguria	Nonspecific	Tubulitis with or without vasculitis[15]	Increase immunosuppression
Renal tumor/PTLD	Uncommon, rare; early or late	Renal impairment, renal mass	Anemia, EBV positive	Atypical cells, mitoses, monoclonality	Minimize immunosuppression, consider chemotherapy

Table 108-1 Differential diagnosis of recurrent glomerulonephritis. *EBV,* Epstein-Barr virus; *PCR,* polymerase chain reaction; *PTLD,* post-transplantation lymphoproliferative disease.

Histologic evidence of recurrence is required in all patients. Biopsy can provide the diagnosis, exclude alternative diagnoses that may require different approaches to treatment, and provide important prognostic information pertinent to the affected graft and also relevant to any future consideration of retransplantation. Full evaluation of the biopsy specimen by light microscopy, immunohistology, and electron microscopy is desirable and in many patients essential to confirm recurrence.[17] Light microscopy and immunohistology are necessary to differentiate recurrent from *de novo* GN, rejection, and calcineurin inhibitor toxicity. The presence of tubulitis should suggest acute rejection. CAN may produce chronic interstitial inflammation and transplant glomerulopathy, which may be indistinguishable from MPGN on light microscopy (Fig. 108-3; see also Chapter 107). The use of immunohistology to define the immunoglobulin and complement component content of immune deposits and electron microscopy to establish the structure of basement membrane and location of deposits may clarify the diagnosis.[17] Histologic appearances are typically no different from the patterns of GN in native kidneys and are illustrated in the relevant chapters of Section IV. The risk of recurrence in common patterns of renal disease is summarized in Table 108-2.

RECURRENCE OF SPECIFIC GLOMERULAR DISEASES

IgA Nephropathy and Henoch-Schönlein Purpura

IgA nephropathy is the most common form of GN leading to ESRD, and affected patients frequently become transplant recipients. Histologic recurrence is frequent and increases with time; one study in which all recipients were subjected to protocol biopsy found recurrence in 58%.[6] Recurrence is difficult to predict. Patient characteristics, pretransplantation course, serum IgA glycosylation, and angiotensin-converting enzyme (ACE) genotype have been found to have no predictive value.[1,6,7] Choice of immunosuppression after transplantation is controversial. One large USRDS registry analysis suggested that individual drug choices did not affect the risk of graft loss attributed to recurrence.[10] In contrast, a recent retrospective analysis of ANZDATA including 1521 allograft recipients who underwent transplantation because of biopsy-proven GN found that continuation of corticosteroids was strongly associated with protection from graft loss caused by recurrence of IgAN, although not from other types of GN.[9] Observational data also suggest that induction with antithymocyte globulin may afford relative protection.[11] Living related donor transplantation has been associated with an increased risk of recurrence and graft loss in some series but not in others,[3] and the avoidance of living related donor transplantation in patients with IgAN is not justified.

The clinical expression of disease is variable and time dependent. Graft loss within the first 3 years after transplantation is uncommon (see Fig. 108-2), although it can occur, particularly when IgAN in the native kidney was rapidly progressive or after previous graft loss resulting from recurrence.[7] The longer-term outlook is not benign, because progressive graft loss over time has been documented by all major studies. In one registry study that included 587 patients with biopsy-proven IgAN, the risk of graft loss from IgAN recurrence was approximately 10% within 10 years after transplantation,[3] although a follow-up study suggests that this risk may be halved in the current era, particularly when corticosteroids are used during the maintenance phase.[9]

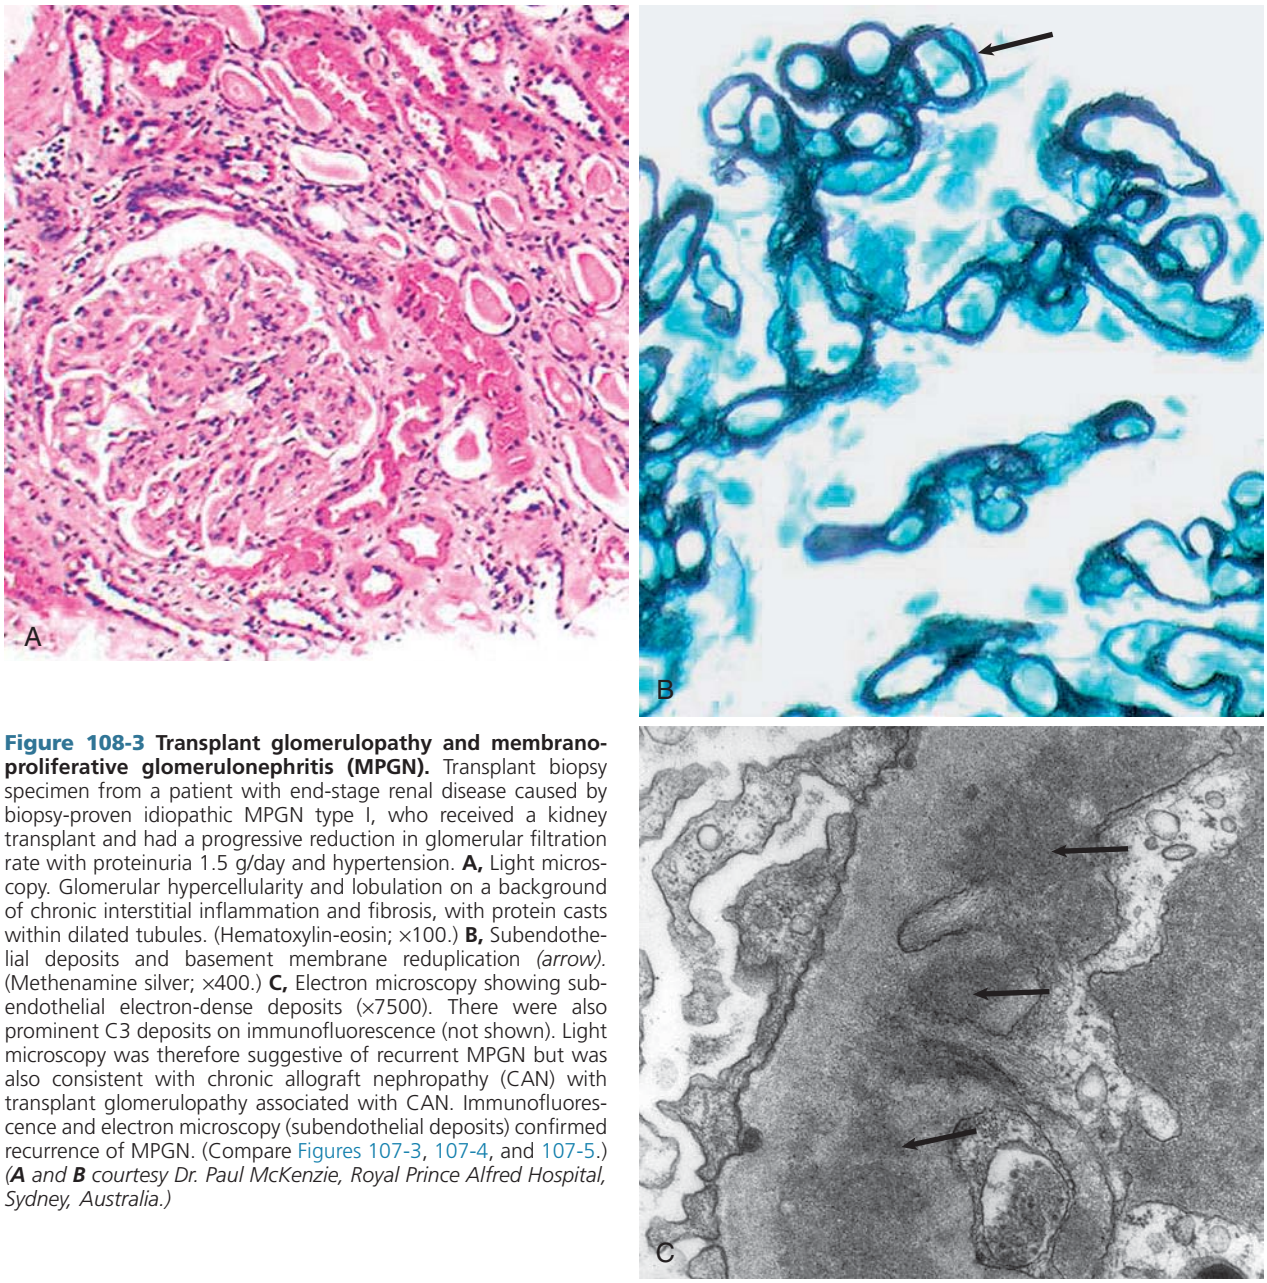

Figure 108-3 Transplant glomerulopathy and membranoproliferative glomerulonephritis (MPGN). Transplant biopsy specimen from a patient with end-stage renal disease caused by biopsy-proven idiopathic MPGN type I, who received a kidney transplant and had a progressive reduction in glomerular filtration rate with proteinuria 1.5 g/day and hypertension. **A,** Light microscopy. Glomerular hypercellularity and lobulation on a background of chronic interstitial inflammation and fibrosis, with protein casts within dilated tubules. (Hematoxylin-eosin; ×100.) **B,** Subendothelial deposits and basement membrane reduplication *(arrow).* (Methenamine silver; ×400.) **C,** Electron microscopy showing subendothelial electron-dense deposits (×7500). There were also prominent C3 deposits on immunofluorescence (not shown). Light microscopy was therefore suggestive of recurrent MPGN but was also consistent with chronic allograft nephropathy (CAN) with transplant glomerulopathy associated with CAN. Immunofluorescence and electron microscopy (subendothelial deposits) confirmed recurrence of MPGN. (Compare Figures 107-3, 107-4, and 107-5.) *(**A** and **B** courtesy Dr. Paul McKenzie, Royal Prince Alfred Hospital, Sydney, Australia.)*

Recurrence of Henoch-Schönlein purpura (HSP) nephritis is less well characterized but appears to be similar to IgAN in all respects. A recent analysis of the United Network for Organ Sharing (UNOS) database including 339 patients with ESRD caused by HSP who received a first kidney allograft reported a frequency of graft loss caused by recurrence of 13.6% and no difference in 10-year graft survival between recipients with IgAN (58.4%) or HSP (59.3%) as their primary renal disease.[18]

Treatment of recurrent IgAN and HSP has not been systematically evaluated. In our opinion, the addition of corticosteroid maintenance in corticosteroid-free patients with recurrence is unproven but reasonable. A change to mycophenolate mofetil (MMF) or the use of fish oil, antiplatelet agents, and tonsillectomy cannot be recommended. The use of nonspecific measures to prolong kidney survival, such as tight blood pressure control, renin-angiotensin system (RAS) blockade, and avoidance of nephrotoxins, is appropriate.

Membranous Nephropathy

The recent identification of the M-type phospholipase A_2 receptor (PLA_2R) as the antigen targeted in idiopathic MN[19] has spurred interest in the use of anti-PLA_2R antibody titers in monitoring disease activity and predicting recurrence. Data on this are conflicting thus far, and further investigation is warranted before adoption of PLA_2R measurement as a clinical tool in transplantation.

Our knowledge of recurrent MN is clouded by two key issues: the small number of patients in reported series and the frequency of *de novo* MN post-transplantation. *De novo* MN has been reported in 2% to 15% of transplant recipients and tends to present more insidiously and later than recurrent MN.[20]

The largest series (pooled from centers in Belgium and France) reported a recurrence rate of 29% in 30 patients at 3 years post-transplantation[21] and graft loss of 38% at 5 years and 52% at 10 years of follow-up. Recurrence is a significant clinical event causing

Recurrent Diseases in Renal Transplants and Effects on Graft Survival		
Disease	**Clinical Recurrence Rate (%)**	**Graft Loss in Recurrent Disease (%)**
Primary focal segmental glomerulosclerosis	20-50 (children), 10-15 (adults)	40-50
Membranoproliferative glomerulonephritis Type 1	20-30	30-40
Dense deposit disease	80	20, often late
Hemolytic uremic syndrome (HUS) Classical D+ HUS Atypical D– HUS Familial HUS	 0-13 30-50 57	 Uncommon 55-100 Approaching 100
IgA nephropathy	30-40, increases with longer duration of follow-up (30%-60% histologic recurrence rate)	16-33
Henoch-Schönlein purpura	Rare (despite 50% histologic recurrence rate)	Rare
Membranous nephropathy	10-29 (histologic recurrence may be more common)	Up to 50
Systemic vasculitis, including Wegener granulomatosis and microscopic polyangiitis	10-20	20-50
Anti-GBM disease (Goodpasture disease)	<5	50
Systemic lupus erythematosus	1-30	Rare
Amyloidosis	25	10-20

Table 108-2 Recurrent diseases in renal transplants and effects on graft survival. *GBM,* Glomerular basement membrane.

proteinuria, nephrotic syndrome, and graft loss in 12% of recipients within 10 years after transplantation.[3] Clinical factors including pretransplantation disease course, duration of dialysis, HLA genotype, graft source, and immunosuppression are not predictive of risk. However, those with a previous graft loss caused by recurrence are at high risk if they undergo retransplantation.[21]

Management of recurrent MN is based on anecdotal reports and extrapolation of data on the management of native kidney MN. There has been some success with rituximab reported in small case series, but the findings await confirmation in a prospective trial. Spontaneous remission appears to be less common than is seen in MN affecting native kidneys. The cumulative exposure to immunosuppressive therapy should be considered because these patients may be at increased risk of lymphoma. Living donor transplantation appears warranted for first grafts but in our opinion should probably be avoided for second grafts if the first was lost early because of recurrence.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis recurs in 20% to 30% of first transplants.[22,23] FSGS is a heterogeneous group of conditions, and those with familial or sporadic forms associated with mutation of slit-diaphragm proteins such as podocin, those with FSGS secondary to vascular disease, and those with a very slow rate of progression are at substantially lower risk, whereas patients with an aggressive initial course (heavy proteinuria and renal failure within 3 years of onset), who are younger than 15 years, who have mesangial hypercellularity on biopsy, or who experienced recurrence in a previous graft are at greatest risk.[22,23] The rate of recurrence is higher than 75% in subsequent grafts when the first graft was lost because of recurrence.[24] Living related donor transplantation has been implicated as a risk factor for recurrence; however, a major analysis of U.S. registry data (USRDS) refutes this notion.[16]

Recurrence occurs early, typically within the first month posttransplantation, and manifests initially with heavy proteinuria, followed by hypertension and graft dysfunction. Patients with recurrent disease appear more susceptible to acute rejection and acute kidney injury,[25] as well as graft loss. Recurrence has been associated with early graft loss in up to 50% of patients[23]; however, the adoption of plasma exchange appears to have delayed graft loss in many patients and decreased the incidence of overall graft failure[3] (see Fig. 108-2).

A circulating 50-kd plasma protein that is bound to immunoglobulin, with an affinity for galactose, appears to cause recurrent FSGS.[26] Soluble urokinase plasminogen activator receptor (suPAR) may be one of the proteins.[27] Attempts to use the presence of the circulating "permeability factor" as a guide to the risk of recurrence have not as yet produced a clinically useful test. Plasma exchange or immunoadsorption with either a protein A or anti-IgG column effectively removes the permeability factor because it is bound to immunoglobulin and as a result provides an effective therapy for many patients who develop recurrent FSGS.[28,29] Although not subjected to a randomized, controlled, prospective trial, several series have reported disease remission in the majority of patients who receive treatment within 2 weeks of recurrence.[23,29] The potential for positive publication bias and the absence of randomized clinical trial evidence make prognostic information speculative; however, in the our assessment, response rates appear likely to exceed 50% when therapy is commenced within 2 weeks of clinical recurrence, with lower response rates anticipated when therapy is delayed. Given that graft survival appears to be significantly prolonged in patients who respond to therapy, a course of plasma exchange is warranted in all patients unless contraindications exist (see Chapter 99). Immunosuppression should include a calcineurin inhibitor, and addition of an ACE inhibitor should also be considered, based on case report evidence. A minority of patients with an incomplete response or relapse after cessation of initial therapy will require repeated or long-term plasma exchange[30] or concurrent treatment with secondary agents such as rituximab or cyclophosphamide.[29,31,32] For such patients we recommend a course of rituximab, 500 mg weekly for 4 weeks, in addition to existing immunosuppression and weekly plasma exchange. Pretransplantation plasma exchange has not been shown to be of benefit in the prevention of recurrence in the graft. See Figure 108-4 for an approach to the management of recurrent FSGS.

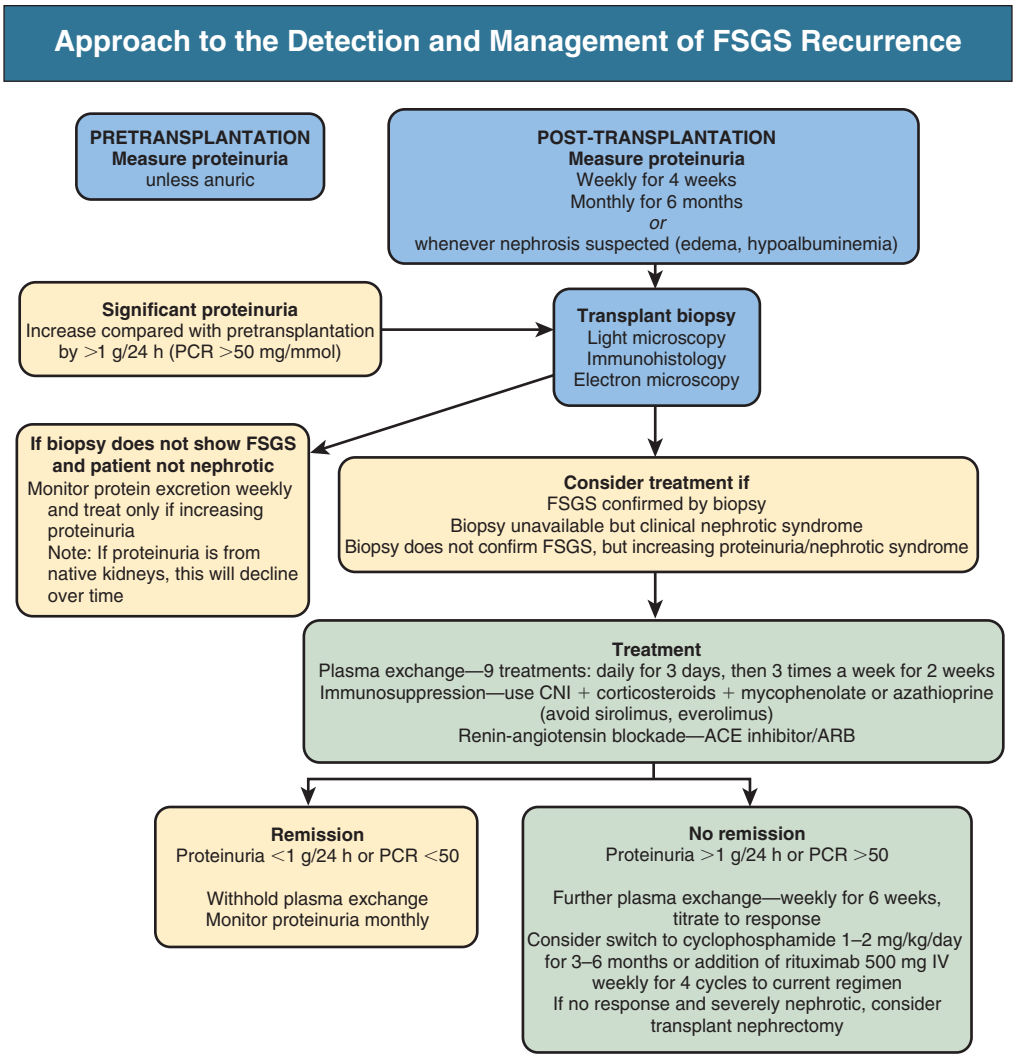

Figure 108-4 Approach to the detection and management of focal segmental glomerulosclerosis (FSGS) recurrence. Author's recommendation based on Davenport.[30] *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNI,* calcineurin inhibitor; *PCR,* urine protein-creatinine ratio, mg/mmol.

Minimal change disease is a far less frequent cause of ESRD. Recurrence of disease after transplantation has been reported; however, it is difficult to be sure that the underlying disease was not FSGS.

Membranoproliferative Glomerulonephritis

Recurrent MPGN bears major clinical and histologic similarities with the subgroup of patients with CAN who have transplant glomerulopathy, and comprehensive assessment of transplant biopsy specimens (see Fig. 108-3 and compare Figs. 107-4 and 107-5) as well as accurate diagnosis of the native kidney disease is crucial in making this distinction (see Table 108-1). MPGN type I, rather than transplant glomerulopathy, is suggested by the presence of crescents on light microscopy, stronger staining for C3 and weaker staining for IgM on immunohistology, and subendothelial electron-dense deposits on electron microscopy.[17] This distinction has important clinical implications, particularly because a recurrence carries a higher risk of subsequent recurrence should retransplantation be considered. A retrospective analysis of renal biopsies that included 70 patients with MPGN suggests that the severity of histologic lesions is predictive of recurrence.[33]

Membranoproliferative Glomerulonephritis Type I

Membranoproliferative glomerulonephritis type I appears to be mediated by glomerular deposition of immune complexes, triggered by exposure to endogenous or exogenous (e.g., hepatitis C virus [HCV]) antigens. Because the antigens are not necessarily removed by transplantation, recurrence of disease is possible and is seen in 20% to 33% of graft recipients.[34] Graft loss has been reported in up to 40% of those with recurrence, and the risk of recurrence in subsequent grafts approaches 80%.[35] Significant geographic diversity in the risk of recurrence is evident, largely linked to the prevalence of HCV, with much higher rates of graft loss resulting from recurrence being reported in areas where the majority of patients with MPGN are HCV positive, such as Spain,[34] as compared with low–HCV prevalence areas, such as Australia.[3] Patients receiving HLA-identical grafts appear to be at increased risk of recurrence in some series[34] but not in others.[3]

No form of treatment is proven, and the underlying cause of recurrent MPGN should be considered in each patient. Prevention may be effective in HCV-associated MPGN, because interferon-based therapy appears to be effective for virus elimination if undertaken while the patient is on maintenance dialysis, and this provides substantial protection from HCV viremia and MPGN recurrence

after subsequent transplantation.[36] By contrast, the use of interferon after transplantation may precipitate acute rejection and should be avoided. Other antivirals, such as ribavirin, may have a role; however, proof is awaited. Other forms of MPGN type I have been treated with immunosuppression or plasma exchange with success in single patients.

Dense Deposit Disease

Dense deposit disease (formerly known as MPGN type II) also has clinical and histologic similarities to transplant glomerulopathy. DDD is suggested by granular staining for C3 on capillary loops without immunoglobulin deposits, and the characteristic ribbon-like intramembranous dense deposits on electron microscopy (see Fig. 22-1).[17] DDD has been found to recur in 50% to 80% of grafts, typically presenting with proteinuria, hematuria, and slowly progressive loss of kidney function.[37] The disease course tends to be slow, and whereas graft loss caused by recurrence is ultimately seen in approximately 20% of patients, this generally occurs beyond the first 10 years after transplantation.[3,37] Graft loss has been associated with male gender, crescents on biopsy, and heavy proteinuria.[37] No effective therapy is known, and although plasma exchange and immunosuppression have been described, these are not warranted in our opinion, and control of blood pressure and proteinuria with renin-angiotensin blockade is the preferred therapy. Given the emerging role of alternate complement pathway mutations in DDD (see Chapter 22), plasma infusion or administration of eculizumab may prove useful in the future.

Membranoproliferative Glomerulonephritis Type III

Recurrence of membranoproliferative glomerulonephritis type III, a rare disease, has been reported and has resulted in graft loss in the longer term.[38]

Congenital Nephrotic Syndrome

Congenital nephritic syndrome of the Finnish type has, in small case series, been reported to recur after transplantation and to cause graft loss; however, it is likely that the mechanism of kidney damage is quite different between primary and recurrent disease. The primary disorder is caused by a mutation of the *NPHS1* gene that results in complete absence of nephrin, and therefore transplantation causes *de novo* exposure to nephrin in the transplanted kidney. Neoantigen exposure causes antibody development and deposition that damages the slit diaphragm and produces a type of MN with podocyte fusion on electron microscopy and a clinical picture of heavy proteinuria and ultimately graft failure. Cyclophosphamide-based rescue therapy may be successful.[39]

Antineutrophil Cytoplasmic Antibody–Associated Pauci-immune Vasculitis

A pooled analysis of all reported case series examining recurrence of ANCA-associated vasculitis, incorporating 127 patients, has largely clarified the behavior of this group of disorders after transplantation.[40] Disease recurrence was detected in 17% of patients after 4 to 89 months of follow-up, with renal involvement demonstrated in approximately 60% of these recurrences and graft losses reported in 25% of these. Clinical parameters were not useful in predicting those patients likely to experience a relapse after transplantation. Pretransplantation disease course, duration of dialysis, ANCA titers at time of transplantation and during follow-up, cytoplasmic ANCA (c-ANCA) or perinuclear ANCA (p-ANCA) pattern, antigen specificity, disease subtype (granulomatous polyangiitis [Wegener granulomatosis], microscopic polyangiitis, or renal-limited vasculitis), and donor source had no significant impact on recurrence rate.[40]

The prevention and management of relapse has not been prospectively examined. In most reports, patients did not receive a transplant until they were in clinical remission; however, successful transplantation in the face of persisting ANCA positivity is well recognized. In the absence of firm evidence, we recommend that clinical remission be maintained for at least 6 months before transplantation to reduce the risk of recurrence and also to avoid the risks associated with performing transplantation in a debilitated patient, especially if ESRD has occurred soon after presentation with systemic vasculitis. Patients with renal relapses have generally been managed with cyclophosphamide-based regimens as used for renal vasculitis in native kidneys, reported to be successful in inducing a remission in 11 of 16 (69%) cases.[40] The negative impact of use of cyclophosphamide to treat relapse has not been reported, but would clearly include a significant increase in the risk of bladder cancer.

Kidney transplantation for ANCA-associated vasculitis is associated with a reduction in the frequency of disease relapse by approximately 50% compared with patients remaining on dialysis, and patient and graft survival post-transplantation is similar to that in other transplant recipients.[40]

Goodpasture Disease

Histologic recurrence of anti-GBM disease (Goodpasture disease) is seen in 50% of patients who receive a transplant while circulating anti-GBM antibodies persist, but rarely when patients undergo transplantation 6 months or more after the disappearance of anti-GBM antibodies. With delayed transplantation, the rate of clinical recurrence is very low, and since the implementation of this practice in Australia, no grafts were lost after transplantation in 47 patients followed for up to 10 years.[3] Rare episodes of recurrence should be treated as for native kidney disease with corticosteroids, cyclophosphamide, and aggressive plasma exchange (see Chapter 24).

Recurrent anti-GBM disease is distinct from *de novo* anti-GBM disease, which is seen in up to 15% of transplant recipients with Alport syndrome who develop anti-GBM antibodies in response to neoantigen exposure (α chain of type IV collagen) via the transplant.[41] This is also discussed further in Chapter 24.

Lupus Nephritis

The reported recurrence rate of LN has varied from 2% to 54% depending on the diagnostic criteria used.[42,43] Recurrence has been reported early (days) and late (years) after transplantation, with a median time to recurrence of approximately 4 years.[42] The clinical and histologic pattern of recurrence is variable but is typically more benign in histology and clinical expression than the patient's original disease. Whereas the majority of patients with ESRD caused by lupus have had diffuse proliferative (class III or IV) LN, mesangial proliferative (class II) LN is the most commonly described lesion post-transplantation, followed by class III and membranous LN (class V).[43] Duration of dialysis and serologic activity before transplantation do not predict recurrence, and antinuclear antibody titer and complement levels are unreliable markers of disease recurrence. There is no consistent relationship between recurrence of nephritis and activity of extrarenal lupus after transplantation.

The long-term outcome for lupus patients after transplantation is controversial but appears similar to that of the general post-transplantation population.[42,44] Although recurrence is an uncommon cause of graft loss within the first 10 years after transplantation, with no cases of graft loss reported from 86 recipients in one registry

analysis,[3] late graft losses do occur. It is clear that lupus patients, particularly those with a lupus anticoagulant, are at increased risk of thrombotic events after transplantation including graft thrombosis.[45]

Management of recurrent LN has not been systematically studied; corticosteroids, cyclophosphamide, mycophenolate, and plasma exchange have been used, with variable results reported. Anticoagulation during the perioperative and early post-transplantation phases should be considered for those with a past history of thrombosis or lupus anticoagulant positivity. Successful retransplantation has been reported after graft loss caused by recurrence.[45]

Thrombotic Microangiopathy and Hemolytic Uremic Syndrome

The diagnosis of recurrent thrombotic microangiopathy (TMA), including HUS, is complicated by the fact that *de novo* TMA is seen in 1% to 5% of kidney transplant recipients, most commonly associated with the use of calcineurin inhibitors (both tacrolimus and cyclosporine carry a similar risk), sirolimus, or OKT3 or with acute vascular rejection. Drug-induced *de novo* TMA is generally observed within 14 days of drug commencement. A meta-analysis that examined 10 reports covering 159 grafts in 127 patients reported recurrence in 28% of grafts, and this was strongly associated with a poor outcome: 1-year graft survival was 33% for those with recurrence versus 77% in those free from recurrence ($P < .001$).[46] Recurrence risk is clearly associated with the underlying cause of TMA. Typical childhood Shiga toxin–associated HUS seldom recurs, whereas recurrence of atypical HUS is frequent and, particularly in hereditary forms associated with mutation of complement components or complement regulatory factors, occurs in up to 80% of patients.[47]

Our understanding of atypical HUS has increased substantially in recent years with the identification of the alternate complement pathway as the central player in its pathogenesis. The risk of atypical HUS recurrence and its impact on graft survival are dependent on the mutation responsible. Mutations in factors H and I are associated with a recurrence risk of approximately 75%, and more than 90% of those with recurrence incur graft failure, typically within the first year.[48] In contrast, mutations of membrane cofactor protein are associated with a recurrence rate of 20% and substantially better survival rates than in patients with factor H or I mutations.[49] Given the variation in risk of recurrence associated with mutations of different complement components, genotypic evaluation of the recipient and any potential living donors before transplantation is advisable for all patients with ESRD caused by atypical HUS.[50] Combined liver-kidney transplantation may be considered in selected candidates with defined mutations.[51] Recurrence is also associated with an older age at onset, rapid progression of the original disease, earlier transplantation, living-related transplantation, and the use of calcineurin inhibitors.[46] Recurrence is generally within the first 6 months after transplantation; however, late recurrences have been reported.[46] The clinical presentation may be gradual or abrupt, with thrombocytopenia, hemolysis, and progressive renal dysfunction.

Whereas *de novo* disease may respond to withdrawal of the inciting agent, management of recurrent disease is uncertain. We recommend withdrawal of any potential causative agent such as calcineurin inhibitors, and if this is not effective after 48 hours, a trial of plasma exchange should be initiated with three half-plasma volume exchanges performed on 3 consecutive days with fresh-frozen plasma used for replacement. Because an increased incidence of acute rejection has been reported in patients with recurrence,[47] inadequate immunosuppression after calcineurin inhibitor withdrawal should be prevented with a temporary increase in the dose of corticosteroids. In patients with life-threatening thrombocytopenia or hemolysis, hematologic stability may be restored by transplant nephrectomy. Eculizumab, a humanized monoclonal antibody targeting C5 of the complement membrane attack complex, is emerging as an effective therapy in the treatment of atypical HUS. In case reports, eculizumab has been reported to be successful in both the treatment of recurrence and prophylaxis pretransplantation. Multicenter Phase II trials are currently under way to evaluate its efficacy. Plasma exchange may be effective in patients with mutations in factors H or I, as well as those who have autoantibodies directed against factor H. However, it may be less effective in patients with mutations of membrane cofactor protein or thrombomodulin, in which the protein is membrane bound. The prognosis with recurrent disease is poor. More than 50% of grafts are lost within the first year, and graft survival beyond 5 years is quite uncommon.[46] There is no evidence that calcineurin inhibitor avoidance is useful in preventing recurrence.

Scleroderma

Limited literature exists because of the rarity of scleroderma. An analysis of 86 patients reported to the UNOS registry after receipt of a kidney transplant because of scleroderma from 1987 to 1997 demonstrated graft survival of 62% at 1 year and 47% at 5 years after transplantation; 24% of recipients died during the 10-year observation period.[52] The recurrence rate could not be accurately determined; however, recurrence was responsible for graft loss in 21% of patients in whom the cause was identified, which is consistent with previously accepted recurrence rates. A recent review of the literature suggests that rapid loss of renal function after diagnosis may predict recurrence in the graft.[53] The effect of transplantation on the extrarenal manifestations of scleroderma has not been well documented. The management of scleroderma after transplantation is unstudied; however, the use of RAS blockade after transplantation to treat hypertension would seem appropriate. Overall, renal transplantation appears to be an appropriate treatment for those with scleroderma and ESRD.

AMYLOID, LIGHT-CHAIN DISEASE, AND FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Amyloidosis

The risk and impact of recurrence for patients who undergo transplantation because of systemic amyloidosis are dependent on its cause. Management of AL amyloid is primarily directed at treating the underlying plasma cell dyscrasia, most commonly by high-dose chemotherapy and autologous stem cell or allogeneic bone marrow transplantation. Recurrence after transplantation is likely to occur if the malignancy is not fully controlled but may be susceptible to further chemotherapy. The largest reported series includes 25 patients who received a kidney transplant for AL amyloid–induced renal failure, of whom 22 had received chemotherapy which placed three patients in complete remission and 13 patients in partial remission at the time of the kidney transplant.[54] Five-year and 10-year graft survival rates were 74% and 25%, respectively. Recurrence in the graft was documented by iodine 123 (^{123}I)–labeled serum amyloid P component scintigraphy in 28% at a median of 5 years after transplant, although no grafts were lost through recurrence. Myeloma recurred in five patients (28%), of whom three achieved complete remission with further chemotherapy. The major cause of graft failure was the death of 13 patients (52%), most commonly caused by sepsis. Cardiac involvement on echocardiogram was noted in five patients before transplantation, and one died of cardiac failure after

transplant. Thus, transplantation appears to be a viable option for patients with ESRD caused by AL amyloidosis, provided they have achieved at least a partial remission after chemotherapy and have little or no cardiac involvement.

Secondary (AA) amyloidosis is typically a more insidious disease; renal failure is a relatively frequent complication, and renal transplantation is frequently effective.[54] The risk of recurrence of AA amyloid depends on the ability to eradicate the underlying cause of chronic inflammation. In AA amyloid, recurrence as a result of chronic infection is unlikely if the infection can be eradicated pretransplantation, whereas conditions such as rheumatoid arthritis may persist after transplantation and lead to recurrent amyloid in the graft. Less than 5% of patients with AA amyloid associated with familial Mediterranean fever, which can be managed with colchicine after transplantation, have recurrence at 10 years after transplantation.[55] A Norwegian series of 62 transplants in patients with AA amyloid, mostly secondary to rheumatic diseases, demonstrated a recurrence rate of 10% at an average of 5 years of follow-up, with recurrence causing graft loss in two patients only. Overall, patient and graft survival rates were 65% and 62%, respectively, at 5 years, with most losses resulting from infection.[56]

Light-Chain Nephropathy

Patients with light-chain nephropathy have occasionally received transplants and recurrence is common; one case series reported recurrence in five of seven patients at a range of 2 to 45 months after transplantation. Those with recurrence developed proteinuria, hypertension, and progressive graft dysfunction. One of seven has had long-term graft function, and one died soon after transplantation because of myeloma.[57] Kidney transplantation is therefore generally inadvisable for patients with this disease, unless performed in conjunction with bone marrow transplantation as a means of curing the underlying disease. Rituximab and bortezomib have been used with success in patients with light-chain nephropathy recurrence in the graft, but insufficient evidence exists to recommend either agent as a standard of care.

Fibrillary and Immunotactoid Glomerulopathies

Fibrillary and immunotactoid glomerulopathies are known to recur in approximately 50% of those undergoing transplantation for these diseases, and although early graft loss as a result of recurrence has been reported, decline in graft function is most commonly slow and does not appear to have an impact on 5-year graft survival rates.[58]

RECURRENCE OF METABOLIC DISEASES AFFECTING THE KIDNEY TRANSPLANT

Diabetes Mellitus

Diabetes mellitus is the most common cause of ESRD in most parts of the world; however, these patients undergo transplantation less commonly than those with GN because of a higher prevalence and severity of cardiovascular comorbidity. Recurrence of diabetic nephropathy is well recognized both histologically and clinically, affecting at least 25% of recipients at an average follow-up of 6 years and with some patients diagnosed within 3 years of transplantation.[59] Histologic and clinical features are similar to those of native kidney diabetic nephropathy. The risk of graft loss from recurrence has not been well documented but appears to be significantly less than with GN, probably because of the competing risk of death from cardiovascular disease. NODAT is also common and has been reported to cause nephropathy in the graft in a similar proportion of patients, also commonly manifesting within 5 years of transplantation. The extent to which this contributes to graft loss also awaits clarification, although a recent analysis of registry data suggests that the impact on graft failure is insignificant in comparison with the impact on premature death with a functioning graft.[5]

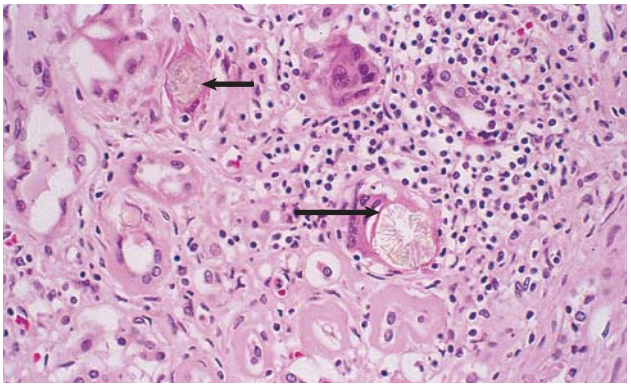

Figure 108-5 Recurrent primary hyperoxaluria. Light microscopy demonstrates oxalate crystals within the tubular lumen *(arrows)* with a secondary interstitial inflammatory infiltrate.

Primary Hyperoxaluria

Primary hyperoxaluria (see Chapter 59) is a rare autosomal recessive disease caused by defective or absent hepatic production of alanine glyoxylate aminotransferase, resulting in systemic accumulation of calcium oxalate (oxalosis). Kidneys and blood vessels in particular are affected. Kidney transplantation alone is frequently complicated by hyperoxaluria and consequent recurrence in the graft and ultimately graft loss (Fig. 108-5). By contrast, combined liver-kidney transplantation corrects the underlying metabolic deficit and permits long-term kidney graft survival. In an analysis of the USRDS that included 190 adults with oxalosis who went on to undergo renal transplantation, 134 patients who received a kidney transplant alone experienced 48% 8-year death-censored graft survival. This was inferior to 56 patients who also received a liver (76%) and inferior to a control group with a primary diagnosis of GN (61%).[60] Aggressive removal of residual oxalate before transplantation by dialysis and after transplantation by pyridoxine supplementation and maintenance of high urine volumes may also decrease the risk of graft damage.

Fabry Disease

Fabry disease results from a defect in lysosomal α-galactosidase A enzyme, which results in tissue accumulation of trihexosylceramide, eventually causing ESRD (see Chapter 48). Recurrent Fabry disease has been documented within the graft; however, graft survival does not appear to be affected. Treatment with recombinant α-galactosidase A, should this become widely available, is likely to reduce the risk of ESRD and also that of recurrence.

RECURRENCE OF VIRUS-ASSOCIATED NEPHROPATHIES AND TUMORS IN THE TRANSPLANTED KIDNEY

Virus-associated kidney diseases may recur following transplantation. Hepatitis B and C virus–associated MPGN and MN are known

to recur; however, the risk of this can be substantially decreased by successful antiviral therapy before transplantation (see Chapter 57).

Retransplantation has been reported in patients experiencing graft loss because of BK virus nephropathy. In the largest series, recurrence was documented in 1 of 10 transplant recipients at an average follow-up of 3 years.[61] Measures to decrease the risk of recurrence included delay in retransplantation by an average of 13 months and transplant nephrectomy in seven patients. Calcineurin inhibitor–based triple immunosuppressive therapy was used in all patients, and the one patient with recurrence experienced stabilization of graft function after a reduction in immunosuppression.[61] Thus retransplantation, ideally delayed until BK virus is not detectable in serum by polymerase chain reaction, appears to be safe and effective.

Patients who develop post-transplantation lymphoproliferative disease and incur graft loss as a result of direct infiltration or rejection after the withdrawal of immunosuppression may safely and successfully undergo retransplantation after a substantial period of recovery. There was no evidence of recurrence reported in one series of five cases.[62]

CHAPTER 109

Outcomes of Renal Transplantation

Jeremy R. Chapman and Deepa Usulumarty

Improving the outcome for patients with end-stage renal disease (ESRD) is the only justification for renal transplantation. If there were not objective and relevant data on outcomes that are meaningful to the patient, then few would take on trust the benefits of a procedure that has the risk of multiple adverse events. The first patients in the 1950s were comparing the potential benefits of transplantation with certain death from ESRD at that time in the absence of dialysis therapy[1]; some chance of life was better than no chance. Today's patients face a more complex decision with excellent dialysis treatment available in many parts of the world, and an improving and much better understood alternative in the form of renal transplantation.

The field of renal transplantation is rich with data, and increasingly sophisticated outcome measures and analyses are available to inform patient decisions. Nevertheless, when a patient is faced with a particular clinical problem, it is still common that the evidence base is insufficient to inform a specific decision. Transplantation guidelines that have been created by a number of societies and by Kidney Disease: Improving Global Outcomes (KDIGO) demonstrate through the grading of evidence that many specific decisions can be informed only by "consensus opinion." At the very least this emphasizes that there is often no right answer; but it also provides a challenge to prove more about the assumptions that are made in clinical practice every day.

This chapter reviews the techniques and factors that deliver the outcome measures available today to inform patients' decision making about renal transplantation.

METHODS OF MEASUREMENT AND ANALYSIS

Types of Outcome Analyses

If the outcomes of 1000 people undergoing transplantation at different times and in different places are measured, some of the patients will inevitably die over the succeeding years. They may die because of the transplant, they may have an accident, or some other intervention may lead to death. How can this be related to the success or failure of the transplant? The most conventional method is to use a Kaplan-Meier plot that yields an actuarial estimate of outcome, as opposed to an actual measure.[2,3] Events—deaths in this case—are recorded and the time to that event from the transplant is measured. The Kaplan-Meier method then uses the time of follow-up for each individual to contribute to the analysis, resulting in a better estimate of what will happen to the entire group of patients and not just the small group of patients who have reached a particular time point. An example of such an analysis is shown in Figure 109-1.[4] When one is comparing two groups of individuals, there may be issues that should be taken into account such as age. For example, if one group had an average age of 30 years and the other 60 years, differing death rates would be predicted from expectations of what would happen in the general, non-ESRD population. Thus it may be important to show "adjusted" results—for example, adjusted for age and gender—to get appropriate comparisons—for example, between the results in different transplant programs. A multivariate analysis will provide the opportunity to adjust the results for all of the factors that, on their own, appear to affect the outcome. In the 1000-patient example, it may be that there are statistically significant differences in death rates if the group is divided based on age, the presence or absence of diabetes, gender, or the center where the patients underwent transplantation.[5,6] With a multivariate analysis, it is possible to see which of these outcomes is influenced by the particular distribution of the others. It may be that one transplant center that appears to have worse results performs transplants mostly on older patients and those with diabetes, whereas another center with excellent results selects only young nondiabetic recipients for transplantation. The multivariate analysis may indicate that both centers would likely achieve the same results if they performed transplants in similar patients.

Half-Life Analysis

The half-life analysis is the second type of analysis that is used to extrapolate results beyond where the data stop. In the 1000-patient example it may be that no one has passed the 10-year mark, yet patients seek an estimate of how long their kidney may last. Actuarial analysis may indicate an 80% chance of a transplant lasting 10 years but does not provide information about what happens after 10 years. A half-life analysis allows extrapolation from the known data. There are two different half-life calculations in the literature: the median survival, which is the time for which the middle patient in the series has survived; and the conditioned half-life, which is the median survival of the patients who have survived 1 year or more. Figure 109-2 provides an example of the use of half-life calculations to demonstrate the difference in outcomes related to human leukocyte antigen (HLA) matching between donor and recipient.[7]

Graft Survival

Graft survival may be presented in two different ways, each valid in its own right, but yielding quite different answers. One of the problems in the field is that many graft survival analyses do not make clear which is being used. It is possible to understand the problem using the 1000-patient example. Assume that 100 patients have died with their transplant still functioning at the time of death and 80 have lost their grafts from rejection and other causes. If one counts death as a cause of graft loss, then 180 of the 1000 patients have lost their grafts; if one ignores death as a cause, then only the 80 have lost their grafts. The latter calculation is best described as *death-censored graft survival,* whereas the inclusive analysis is described as *patient and graft survival.* When the analysis is not specified, the

findings can be misleading and may make no sense. For example, in the illustrative analysis, the actual patient survival would be 90% (100 deaths in 1000 patients) and the death-censored graft survival would be 92% (80 grafts lost in 1000 transplants), so it might be concluded that 2% or 20 kidneys somehow survive in the absence of the recipient! Both approaches are of course relevant to different situations—on the one hand to understand what causes kidneys to fail, and separately to understand what causes patients to die—but there must be methodologic clarity.

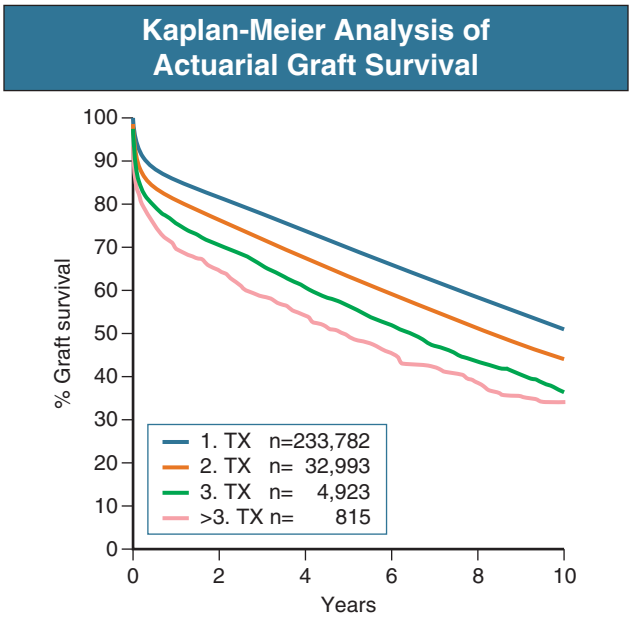

Figure 109-1 Kaplan-Meier analysis of actuarial graft survival. Collaborative Transplant Study analysis of actuarial survival of deceased donor renal transplants 1985 to 2011 by recipient graft number (1, 2, 3, and >3). *(From the Collaborative Transplant Study, University of Heidelberg, Department of Transplantation Immunology. CTS outcome graphs. Available at www.ctstransplant.org/public/graphics.shtml. Accessed January 7, 2013.)*

Randomized Controlled Trials

Randomized controlled trials (RCTs) are a conventional way of determining differences between two or more therapies and are used in transplantation especially to evaluate new pharmaceutical products, which require testing in randomized studies before they can be registered for use. The majority of RCTs therefore compare two drug regimens—one with and one without the new agent. Two critical problems compromise the value of RCTs in renal transplantation: First, the relatively small number of transplants performed in any one center means that it is hard to mount studies with sufficient power to detect significant differences; and second, good early surrogate markers for long-term outcomes are lacking. In cardiovascular studies, in contrast, it is often possible to randomize many thousands of patients and detect differences in meaningful outcomes other than death; and in cancer studies it is possible to use short-term evidence of tumor response as a surrogate for longer-term outcomes. In an earlier era of renal transplantation, relatively small studies could be highly informative. An example of an RCT from the 1980s is the Oxford cyclosporine trial,[8] in which azathioprine and prednisolone could be compared with cyclosporine with sufficient power to detect a difference with less than 100 patients randomized to each group. This was because the survival rates in the control arm were susceptible to large improvements—5-year graft and patient survival improved by 20% from a baseline around 47% to 67% with the addition of cyclosporine. Today the results of standard of care therapy are so high that recruitment of sufficient patients to detect either graft or patient survival differences at 1 or 2 years is not only extremely expensive but, unless the trials are very large, likely to founder on small random variations in such issues as surgical complications.

In the 1990s the introduction of the composite end point controlled the required size of RCTs. The composite end point is an acceptable indicator of benefit for the U.S. Food and Drug Administration (FDA) and other regulatory authorities to register a drug for therapeutic use. The composite end point includes patient death, graft loss, acute rejection episodes, and loss to follow-up (the last index conservatively defaults the patients who are lost to follow-up as having failed the therapy). Analysis is by intention to treat—in

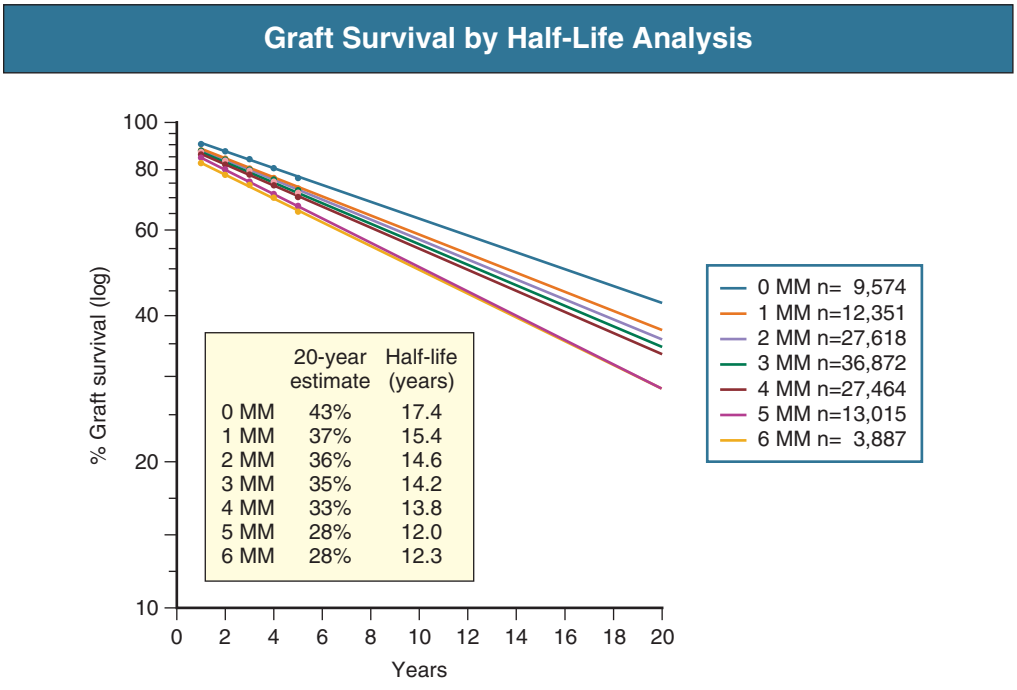

Figure 109-2 Graft survival by half-life analysis. Collaborative Transplant Study analysis of survival of first deceased donor renal transplants performed from 1985 to 2011 by human leukocyte antigen (HLA) mismatch *(MM)* showing the half-life calculation and 20-year estimates of survival. *(From the Collaborative Transplant Study, University of Heidelberg, Department of Transplantation Immunology. CTS outcome graphs. Available at www.ctstransplant.org/public/graphics.shtml. Accessed January 7, 2013.)*

other words, for outcome analysis the patient is assigned as randomized whether or not the patient ever received the assigned treatment. Three key studies confirming the benefit of mycophenolate mofetil (MMF) were conducted using this approach and recruited around 500 patients allocated randomly into three study arms.[9,10]

Moving forward another 10 years, the largest transplant RCT undertaken to date (the Symphony trial[11]) required more than 1500 patients to be randomized, and even then was powered only for a surrogate marker of long-term outcome, differences in renal function. It is now accepted that transplant RCTs cannot be sufficiently powered to detect differences in the "hard" end points of patient and graft survival and must all be powered for a composite end point and surrogates of long-term outcomes. Which short-term surrogates provide good predictors of long-term outcomes has yet to be determined. Acute cellular rejection was, in the 1990s, a short-term measure of importance for long-term results, but perhaps not when current immunosuppressive regimens are used.[12]

Cohort Studies

Some clinical issues are not susceptible to testing by RCT. For example an RCT design will never be able to test whether cancer is more prevalent in patients on dialysis compared with patients after transplantation, first because randomization to dialysis or transplantation is ethically unachievable, and second because the numbers required to power such a study would exceed global transplant capacity. However, it is still important to understand whether the risks change between dialysis and transplantation and thus to understand whether there is any action that can increase or decrease death from cancer after transplantation. An example of an analysis addressing these questions is the Australian cancer study in which data from the Australia and New Zealand Dialysis and Transplant (ANZDATA) registry on a cohort of patients who were first treated for ESRD between 1982 and 2003 were linked to data from the national cancer registries.[13] It is critical to ensure the selection of the cohort is appropriate to the question being asked. All too often a cohort study is selected from a convenience sample and thus has critical systematic flaws. A typical convenience sample is "all patients being followed by a particular transplant unit." The analysis becomes an assessment only of patients still alive and still coming to the transplant unit for follow-up. The cohort has been distorted, the flaw being that the patients not being followed, because of death or graft failure, may be crucial to the analysis.

Meta-Analyses

Some areas of transplantation are rich in both RCTs and nonrandomized studies of a particular intervention—for example, interleukin-2 (IL-2) receptor blockade for induction in renal transplantation. Because the studies have produced variable results, which one should be believed? This issue is approached by meta-analysis of available studies and exemplified by the work of the International Cochrane Collaboration.[14] An example of a Cochrane review is shown in Figure 109-3.[15] These types of analysis combine the results from patients who have undergone the same interventions from all similar studies, which thus gives much greater statistical power than each study alone can provide. The methodology requires searching for all studies of the question and especially capturing unpublished studies. The problem of publication bias plagues the field; studies with a positive finding for the intervention are more likely to be published than negative studies. The compulsory preregistration of all trials of a drug by commercial entities in a public database such as

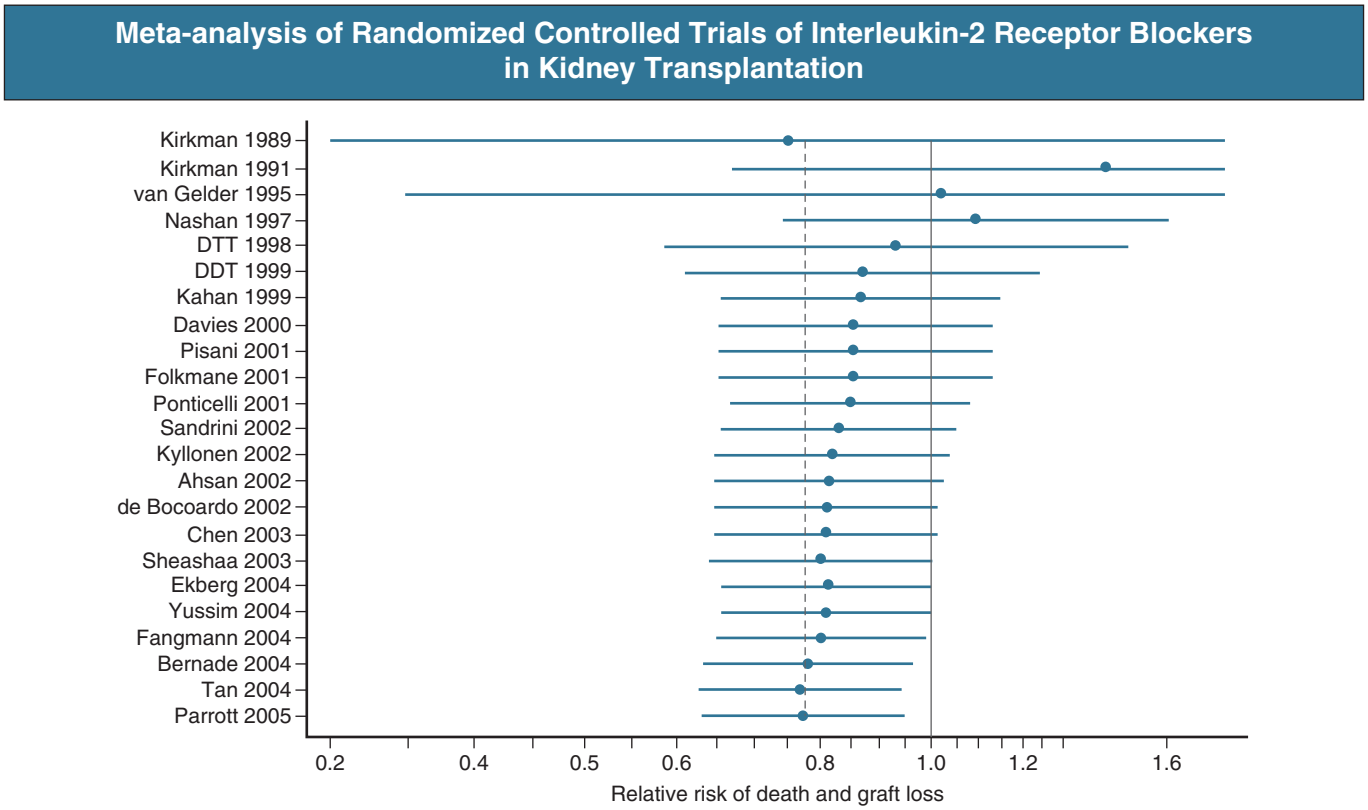

Figure 109-3 Meta-analysis. A cumulative meta-analysis showing the effect of increasing numbers of trials on the confidence intervals of the outcome of death and graft loss in patients receiving interleukin-2 receptor blockers compared with placebo in all randomized controlled trials published from 1989 to 2005. *(Data reproduced with permission from and courtesy A. Webster, presented at the World Transplant Congress, Boston, 2006.)*

www.clintrials.gov is designed to avoid this publication bias, and it is now widely accepted that nondisclosure of data by commercial sponsors of clinical trials is neither scientifically acceptable nor tolerated by the regulators.

Case Reports

Can a case report provide valuable information about outcomes after transplantation? There are some instances of rare events where the knowledge from a case report has proved important. One example is the early anecdotal reports of hepatitis B transmission from hepatitis B surface antigen (HBsAg)–negative donors to recipients of their livers.[16] A few case reports led to a cohort analysis, which in turn led to an understanding that hepatitis B can be transmitted from a donor who tests negative for HBsAg but positive for hepatitis B core antibody. The surveillance and vigilance strategy for the safety of cells, tissues, and organs of human origin is based on this concept—identifying and publicizing the rare cases so that the problems can be recognized (see www.notifylibrary.org).

Expert Opinion Guidelines

The final type of analysis that is pervasive in the transplantation literature is expert opinion, sometimes leading to clinical practice guidelines. Only the major questions have answers in RCTs, meta-analyses, or cohort studies. The clinician is faced with unanswered questions in day-to-day clinical decision making. Guidelines rate the available evidence on particular questions from good to nonexistent. An example of a widely disseminated set of guidelines is the KDIGO guidelines for the care of a transplant recipient,[17] which clearly set out the limits of knowledge in the area. Much of the guidance provided on how to maximize outcomes for particular patients is based on the combined wisdom and experience of clinical practitioners and not on RCT or other data analyses.

Qualitative Studies

Some questions are not amenable to quantitative data collection yet are of great importance to the field. What causes potential living donors to decide to donate? What do physicians consider most important in assessment of living donors? Why does a particular community not donate many organs after death? These questions are amenable to qualitative research and can be assessed and measured, not to produce proof related to a particular question, but to generate testable hypotheses. Qualitative studies create insights into behaviors and attitudes and do not assume that there is a single reality to be discovered; people have different views on organ donation, and any system of measurement that expects everyone to be driven by the same perspectives is going to be disappointed. A guide to the approach of qualitative studies in transplantation has been published to assist scientists familiar mostly with quantitative studies.[18]

Types of Data Collection

All analyses of data are dependent on the methodology of data collection and completeness of the data. Clearly if the data entered into an analysis are flawed in some way, then the analysis will simply embed those flaws and provide spurious confidence in the outcomes of the analysis. Once the flaws of data collection have been hidden by an analysis, it is all too often that they are never again identified and clinical practice is influenced on the basis of a false assumption. It is thus essential that the reader of any analysis verify for himself or herself whether the data were collected in a manner that is trustworthy and relevant to the question. There are many ways to collect data, all of which have their usefulness when applied in the right manner.

Registries

The methodology of registry data collection varies from voluntary to compulsory and from automated to manual. The completeness of data is related to the amount collected, the frequency with which it is updated, and the methods used. National transplantation registries, such as the ANZDATA registry in Australia and New Zealand[19] or the similar Malaysian Dialysis and Transplant Registry, are often voluntary. Some, such as the North American UNOS (United Network for Organ Sharing), database are mandatory, in that financial penalties are threatened for failure to fill in critical data elements.[20] The largest international registry is the Collaborative Transplant Study run from Heidelberg, Germany, which uses voluntary data collection on the repeatedly stressed basis that all sequential transplants are entered and followed.[4] Donor registries tend to be complete because they capture all data at the time of organ donation as a part of the process of donation.[21] Registries that collect their data in a manner that is integrated into the process they are measuring, such as taking data directly from the patients' medical records, as in Hong Kong, tend to have the most reliable data. In the United States, the Scientific Registry of Transplant Recipients (SRTR) has the opportunity to use data linkage between databases to increase its accuracy.[22] Data available to SRTR include deaths in the United States and Medicare billing data to cross-check whether a transplant recipient is being billed for dialysis—both useful pieces of information to construct an accurate view of survival of either the patient or graft.

Incompleteness of follow-up data is a weakness of many transplant registries and depends on the ability of transplant programs to follow their patients and to report outcomes. Both steps are fraught with failure. Many patients move among physicians and thus lose contact with the transplanting center; and of course, many transplant centers are pressed for resources, so the voluntary and unpaid activity of completing data returns receives minimal attention. Regrettably, successful outcomes can be artificially inflated by centers that assume patients are alive and well unless they have heard otherwise: bad data thus produces apparently good results.

Registries usually seek at least one data point annually that confirms the patient has been seen and the graft is still functioning; failing that, they define the patient as lost to follow-up at the point of last contact. This technique yields the most benefit from the data that are known about any one individual but does not allow uncertain data to contribute to analyses.

International Statistical Collections

The most useful international statistics collections are those conducted by the World Health Organization and published on the Global Observatory on Donation and Transplantation (GODT) website (www.transplant-observatory.org). These data are contributed by all national governments and represent probably the best estimates of global transplantation activity, but little or nothing regarding outcomes is available from that source. The GODT does allow analysis of relationships between donation and transplantation indices on the one hand and national health and financial statistics on the other, as in Figure 109-4.

Randomized Controlled Trials

The techniques of data management for commercially sponsored clinical research probably supply the most robust of all the data that are available, because the primary data source is the patients' medical records, which are used to record specific items of carefully predefined data and most crucially are audited for accuracy. These three elements—primary data source, predefined information, and auditing—deliver the most trustworthy data. There is, however, one

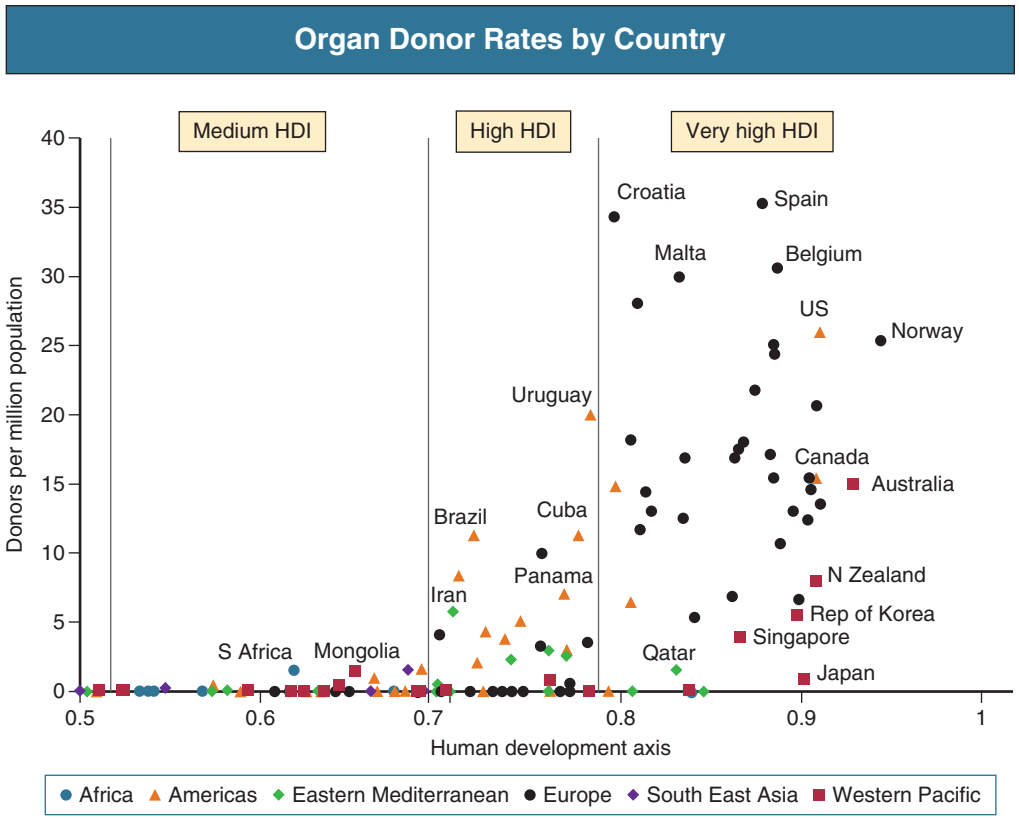

Figure 109-4 Organ donor rates by country. World Health Organization (WHO) analysis of the number of organ donors plotted against the Human Development Index (HDI) for each member state. *(Data reproduced with permission from the Global Observatory on Donation and Transplantation.)*

major drawback: The predefined duration of the studies ensures that data needed to answer questions about the long-term outcomes are almost always missing. The longest clinical trial data collections are usually for only 5 years. An exception, in Australia, is the case of two RCTs in which patients have been followed for up to 20 years through the use of the ANZDATA registry.[23,24]

Structured Reviews

Structured literature reviews are derived from medical reference literature search engines such as PubMed and Embase. There are also two transplantation-specific databases of published clinical trials in the Cochrane Collaboration[14] and the Transplantation Library.[25] These databases contribute the majority of information for the structured literature reviews needed for meta-analyses and guideline development, but nonautomated searching of conference proceedings and abstracts is also needed to ensure complete data identification. The final source of data for questions related to registered therapeutic products is pharmaceutical companies.

VARIABLES AFFECTING THE OUTCOMES OF TRANSPLANTATION

Deceased Donor Variables

The best transplant outcomes have been assumed to come from transplantation of kidneys from young adult male donors with simple trauma as the cause of brain death and with no other medical conditions. These were the donors with which the majority of transplant programs commenced and which have become increasingly rare as road safety, accident retrieval, and neurosurgical interventions have all improved. The older recipient with previous medical conditions who finally dies from a cerebrovascular accident after many years of uncontrolled hypertension has had organs transplanted warily and somewhat reluctantly, usually into an older recipient. An analysis in the United States demonstrated that these extremes yield a twofold difference in graft survival.[26] Four donor factors provide the clearest distinction of outcome: donor age, cerebrovascular cause of death, a history of hypertension, and renal function at the time of donation. These criteria provide a matrix of relative risk of graft failure that ranges from 1.00 for a 10- to 35-year-old donor with no adverse features to a nearly threefold increased risk of failure (2.69) for a donor over age 60 with a cerebrovascular accident, a history of hypertension, and a terminal serum creatinine over 1.5 mg/dl. These criteria were grouped to simplify the definition of a donor kidney likely to be associated with worse graft outcomes as the expanded-criteria donor (ECD) using a cutoff of a 1.7-fold worse outcome; all other donors are classified as standard-criteria donors (SCDs) (Table 109-1).

Expanded-Criteria Donors and Graft Failure

				Donor Age 50-59 yr	Donor Age ≥60 yr
No comorbidity	—	—	—	1.41	1.90
One comorbidity	CVA	—	—	1.61	2.17
	—	HTN	—	1.60	2.16
		—	Creat	1.53	2.04
Two comorbidities	CVA	HTN	—	1.83	2.47
	CVA	—	Creat	1.75	2.37
	—	HTN	Creat	1.75	2.37
Three comorbidities	CVA	HTN	Creat	1.99	2.69

Table 109-1 Expanded-criteria donors and graft failure. Relative risk of graft failure with expanded-criteria donors in the United States, 1999 and 2000. Relative risk is compared with graft failure with donors aged 10 to 39 years with no adverse factors: relative risk = 1.00. Relative risk increases with increasing donor age and presence of one or more of three comorbidities: death from a cerebrovascular accident *(CVA),* donor history of hypertension *(HTN),* or terminal predonation serum creatinine >1.5 mg/dl *(Creat).*

Patient Survival After Transplantation with Expanded-Criteria Donor and Standard-Criteria Donor Kidneys

Recipient Age	ECD		SCD	
	1 Year (%)	5 years (%)	1 Year (%)	5 Years (%)
35-49	96	78	97	85
50-64	89	63	92	75
65+	86	55	89	59

Table 109-2 Patient survival after transplantation with expanded-critera donor (ECD) and standard-criteria donor (SCD) kidneys. Patient survival (percent) after receiving an ECD versus an SCD kidney in the United States, 1999 and 2000. *(Based on data from reference 26.)*

The survival of recipients who received ECD grafts was 91% at 1 year compared with 95% for SCD grafts, but because these kidneys had been allocated to older recipients, the results were not directly comparable. However, by comparing within age cohorts it can be seen that there was a reduced patient survival after transplantation of a kidney from an ECD (Table 109-2). In a separate analysis it has been shown that the mean creatinine clearance 6 months after transplantation declines from approximately 65 ml/min if the donor was 20 to 25 years old to only 35 ml/min for donors older than 70 years.[27]

The approach to allocation of such ECD kidneys varies around the world. The Eurotransplant policy is to allocate older donors to older recipients.[28] In contrast, the Australasian allocation policy does not distinguish among donor ages, but refusal of offers by younger patients leads to organs being accepted only by older recipients, unless a particularly beneficial HLA match or a negative crossmatch occurs in a highly sensitized patient and motivates a younger patient to accept an ECD offer.[29]

Donation after circulatory arrest (donation after cardiac death [DCD]) rather than after a diagnosis of brain death (donation after brain death [DBD]) now accounts for up to 20% of kidney donations in some countries. It has thus become important to determine the impact of DCD on short- and long-term outcomes. The data are reassuring in that although DCD kidneys more often suffer delayed graft function, neither graft survival, patient survival, nor renal function is different from that in transplantation of DCD kidneys from donors under the age of 45 years compared with donation after brain death.[30] Markov modeling has demonstrated that the combination of DBD and DCD donation is economically superior to a simpler strategy that focuses only on the use of DBD kidneys.[31]

Living Donor Variables

The assessment of the living donor is primarily directed at donor safety to ensure the risk to the donor is minimized as much as possible. The secondary assessment is of factors that may affect the recipient's chances of a successful outcome. Impaired renal function and significant donor hypertension and diabetes are, for example, usually exclusion criteria based on donor safety rather than recipient outcomes.[32] Assessment of the living donor is further discussed in Chapter 102. The cumulative data from almost all studies show that transplantation of a living donor kidney offers superior outcomes to deceased donation, though the precise reason for this is probably a mixture of recipient and donor factors including the ability to perform preemptive transplants with living donors. A long-term analysis performed by ANZDATA shows there was a 10% advantage to living donation at 1 year stretching to a 14% advantage by 20 years after transplantation (Table 109-3 and Fig. 109-5).[33]

Graft Survival After Living and Deceased Donor Transplantations

Years	1	5	10	15	20
Living donor	91	75	61	45	35
Deceased donor	81	66	47	33	21

Comparison of the Long-Term Outcomes of Transplantation by Era in Australia and New Zealand After Living and Deceased Donation

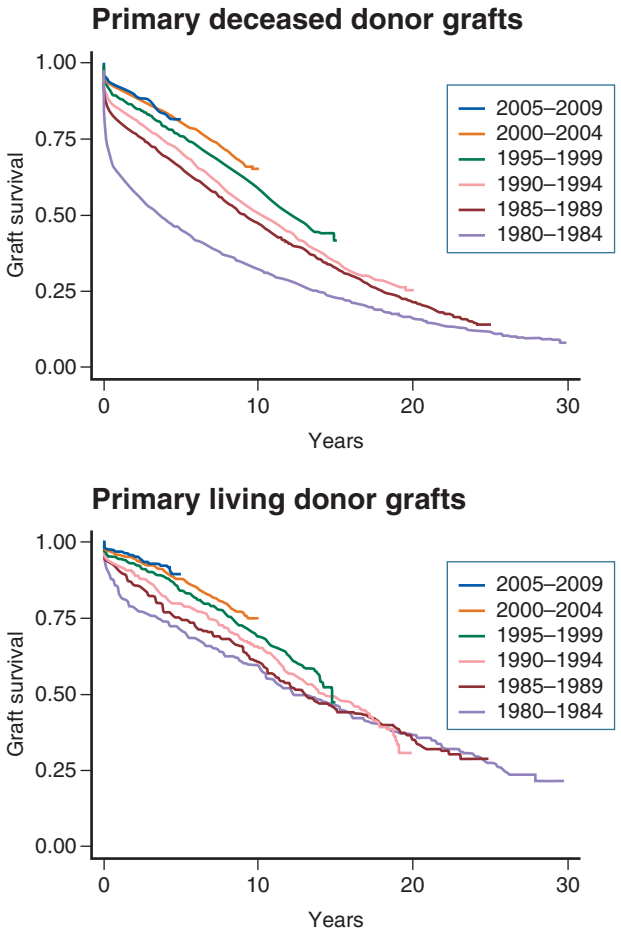

Figure 109-5 Comparison of the long-term outcomes of transplantation by era in Australia and New Zealand after living and deceased donation. *(From reference 19.)*

Other Donor Variables

Additional donor-related factors are known to affect both long- and short-term graft and patient outcomes, such as those that lead to initial nonfunction and determine whether or not the recipient will need dialysis postoperatively (Box 109-1).

Recipient Variables

Many factors that affect both patient and graft outcomes relate directly to the recipient, some of which may be modifiable and some of which are intrinsic. Perhaps the most modifiable factor in theory would be when to get a transplant—before the need for dialysis (preemptive transplantation) or after dialysis has commenced. The analysis of the benefit of preemptive transplantation is complex because the comparison cannot be between people receiving preemptive transplants and those who undergo transplantation after dialysis, because the delayed patients have to survive long enough to be offered a transplant. Despite these complexities of lag time in analysis, there is both an economic argument (it is cheaper to avoid dialysis) and a survival advantage (patients with preemptive transplants have 5% to 10% better 5-year survival after transplant). Equity of access to preemptive deceased donor and living donor transplants is another important factor. Figure 109-6 shows the Australian experience with access to a living donor transplant; people in the higher socioeconomic demographics have a greater chance of a preemptive transplant and greater total access to living donor transplants.

The variously modifiable and unmodifiable factors influencing graft outcomes are shown in Box 109-2, with body mass index (BMI) illustrated in Figure 109-7.[34] In assessment of individual outcomes, there are unfortunately no simple tables of risk analogous to cardiovascular risk profiles for the general population, but the dominant features affecting outcomes are recipient age and cardiovascular comorbidities.

Donor Factors Influencing Recipient and Graft Outcomes

- Deceased versus living donor
- Donation after cardiac arrest (DCD) compared with donation after brain death (DBD)
- Increasing donor age
- Prior donor history of hypertension or diabetes
- Cause of donor death—cerebrovascular disease or prolonged anoxia or drowning
- Female gender compared with male
- Nephron mass (donor-recipient weight ratio)
- Histology (% sclerosed glomeruli)
- *Ex vivo* perfusion not used
- Transmissible disease (infection, malignancy)
- Worse terminal renal function
- Use of inotropes before donation
- Duration of final intensive care admission

Box 109-1 Donor factors influencing recipient and graft outcomes. These donor factors are known to worsen graft and/or patient outcomes after renal transplantation.

Effects of Immunosuppression on Transplant Outcome

There are many examples of the use of outcome analysis to determine alternatives for immunosuppressive therapy after renal transplantation.[8-11,35,36] The proliferation of alternative immunosuppressive therapeutic regimens has yet to be resolved in the way that

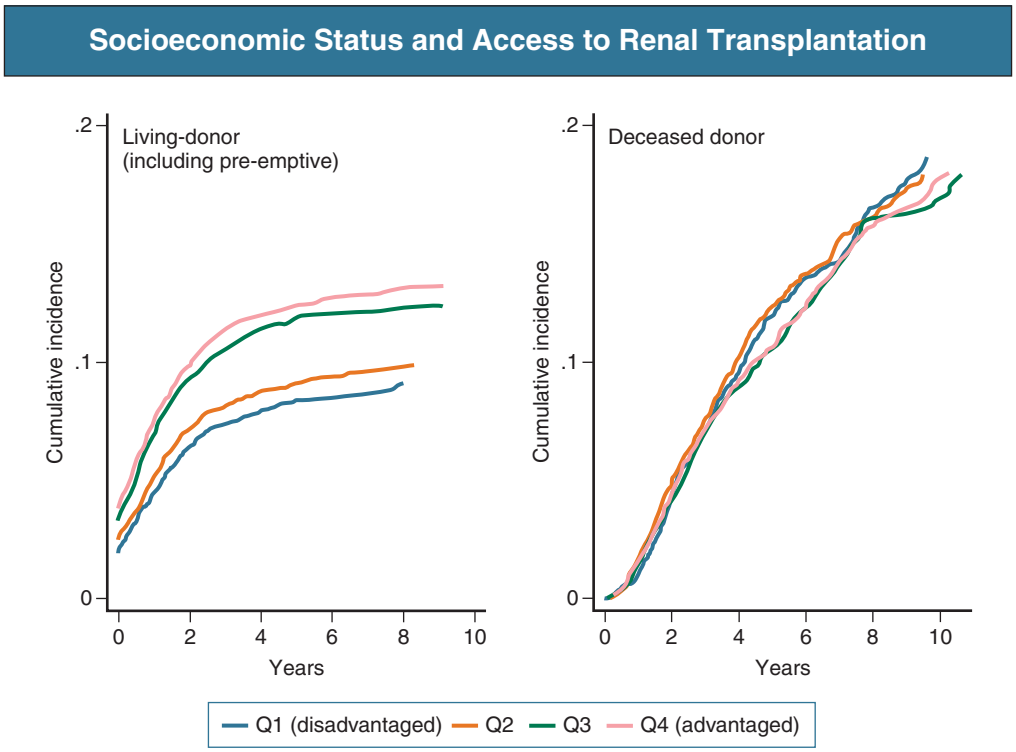

Figure 109-6 Socioeconomic status and access to renal transplantation. Access to transplantation in Australia and New Zealand, 2000 to 2010, by socioeconomic status expressed in four quartiles (*Q1,* most disadvantaged, to *Q4,* most advantaged). Living donor transplants were accessed more frequently and sooner by the top two socioeconomic groups *(Q1, Q2);* approximately 25% of living donor grafts were preemptive. There was no effect of socioeconomic status on deceased donor outcomes (no preemptive deceased donors included). *(From reference 19.)*

Recipient Factors Affecting Graft and Patient Survival After Renal Transplantation

Patient-Related Factors

Age

Adults: Outcome worse with increasing age

Children: Outcome worse <7 kg

Gender: Better outcomes from male donor to female recipient, presumably based on nephron mass.

Race: Worse outcomes compared with whites in United States for African Americans, but better for Asians. Variable effects in other countries but generally worse for indigenous races.

Anti-HLA antibodies: Worse with increasing sensitization because of previous blood transfusions, pregnancies, grafts.

Previous transplants: Worse outcomes with second and subsequent grafts.

Primary renal disease: Specific risks of recurrent disease by type of primary disease.

Comorbidities: Worse outcome with cardiovascular disease, chronic respiratory disease, diabetes mellitus, hepatitis B, or hepatitis C.

Body mass index: Worse outcomes at extremes of BMI: below 20 and above 35 (see Fig. 109-7).

Medication and clinical follow-up adherence: Worse outcome with poor adherence to follow up and medication protocol.

Transplantation-Related Factors

Surgical experience: Worse outcomes with inexperienced surgeons.

Graft and patient vascular anatomy: Worse outcomes with multiple arteries and veins.

Warm ischemia time: Worse outcome with prolonged time.

Cold ischemia time: Worse outcome with prolonged time.

Transplant center experience and results: Most apparent center effects are related to patient and donor selection criteria rather than center expertise. However, some centers in some countries do produce worse outcomes based on multivariate analysis of all relevant factors, leaving center expertise the most likely remaining outcome variable.

HLA matching: Worse outcome with poor matching.

Donor-specific antibodies: Easily detected high-titer anti-HLA class I and class II antibodies detected by cytotoxicity crossmatch tests are associated with hyperacute, accelerated, and acute rejection. Anti-HLA antibodies detected only by solid phase assay depending on their titer are associated with worse long-term outcomes.[42]

Box 109-2 Recipient factors affecting graft and patient survival after renal transplantation. There is significant variation in some of these factors in different countries. *BMI,* Body mass index; *HLA,* human leukocyte antigen.

cancer chemotherapeutic regimens have been defined with specific strategies for specific indications. The standard immunosuppressive therapy against which comparisons must be made in current practice includes a calcineurin inhibitor—generally assumed to be tacrolimus, despite some reluctance by the FDA to accept it over cyclosporine; MMF or mycophenolate sodium; and corticosteroids. The choice of immunosuppressive regimens is discussed further in Chapter 104.

The adverse outcomes of immunosuppression such as excess cancer risk[13] and observations of reduced cancer risk with inhibitors of the mammalian target of rapamycin (mTOR),[37] have led to the individualization of therapy for those with a high risk of skin cancer.[38] This is discussed further in Chapter 105.

Body Mass Index and Graft Loss

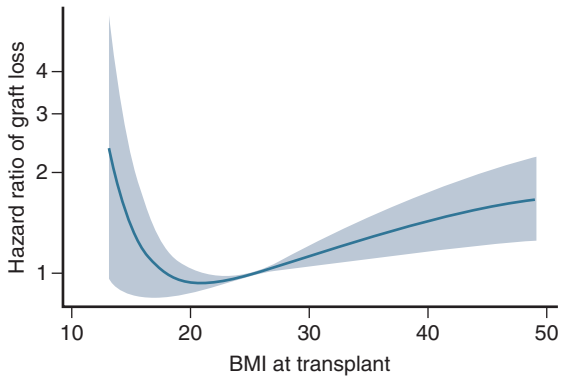

Figure 109-7 Body mass index *(BMI)* and graft loss. Univariate analysis of graft loss by body mass index in 5684 patients in ANZDATA from 1991 to 2004. *Blue line* shows hazard ratio of graft loss; *shaded area* shows confidence intervals. Obesity was not associated with cardiovascular disease (CVD)–related mortality and was associated with age, male gender, smoking, diabetes, CVD, and long-term dialysis ($P < .001$). *(From reference 34.)*

Transplant Center Variables

The outcome of transplantation in different transplant centers is largely, but not entirely, driven by patient selection. In the United States a center-based report card has been used to identify low-performing centers (which have statistically significant worse outcomes than predicted from their case mix). Some of these centers remain low performing and perform fewer transplants after a low-performance report, suggesting that the information about poor outcomes assists both patients and administrators in identifying problems and avoiding transplantation at those centers, but sadly not that the report leads to changes in a low-performing center to turn it into a high-performing center.[6,39]

Transplantation Matching Variables

Human leukocyte antigen matching is perhaps the most dominant feature of individual patient outcomes, with 15% 5-year differences in graft survival quite common across different analyses (see Fig. 109-2).[7,40] The advent of specific definition of anti-HLA antibodies through solid phase assays—especially those using beads read by dual-laser flow cytometry[41]—has increased the precision of HLA typing and HLA matching. However, a critical question remains that has not yet been amenable to long-term outcome analysis: At what sensitivity level and against which HLA antigens should an anti-HLA antibody be avoided? A recent consensus meeting helped to define the knowns and unknowns but has not yet led to a conformity of HLA matching and crossmatching criteria.[42] Desensitization of patients with anti-HLA antibodies has been shown to be a successful way of performing transplantation in patients who would otherwise not be candidates for the procedure,[43] and is discussed further in Chapter 104.

The blood group barrier, once thought immutable, is like the HLA antibody barrier—amenable to intervention providing the titer of anti-ABO antibody is known and reduced by physical removal to a low level at the time of transplantation.[44] The data support the view that antibodies to both HLA and blood group substances may be tolerated once the graft is *in situ* because continued activation of complement is seen in ABO-incompatible grafts but without obvious pathologic graft damage.[45]

OUTCOMES INFORM THE RECIPIENT DECISION

Each patient with progressive end-stage chronic kidney disease must decide whether he or she wishes to commence dialysis, receive a transplant, or elect not to be treated. The outcomes of the alternatives are obviously critical to that decision, and thus it is the responsibility of the treating physician and team to ensure that each patient is properly informed to make that choice. The components of that decision, of course, extend beyond the medical facts and in many countries involve financial and other social factors such as availability of therapy. The medical decision for each individual revolves around prognosis related to comorbidities, organ availability (of both living and deceased donor kidneys), and alternative dialysis therapies. The advantages are not all exactly as might be predicted. For example a 25- to 35-year-old adult with no comorbidities can be predicted to do well after transplantation with either a living or a deceased donor, but such an individual will also do well on dialysis, so the life-year gain from transplantation may not be as much as expected. On the other hand, a 55-year-old diabetic patient may have a poor prognosis with a transplant but will do even worse on dialysis and thus may wish to seek the added life-years from transplantation. This question has been addressed with use of the UNOS databases. Analysis of the additional donor and allocation factors related to prognosis after transplant show that the most life-years accrue when a simultaneous pancreas and kidney transplant is performed in a younger type 1 diabetic recipient and that even an SCD kidney given to an older patient may result in only an additional 2 or 3 years of life compared with dialysis.[46]

These analyses inform the debate about the use of a donated kidney either with or without a pancreas and to whom it should be offered. Outcome data and data analysis are there to assist the transplant community to make judgments about who gets which opportunities—and for the individual, when the opportunities are offered, whether he or she should accept them.

CHAPTER 110

Pancreas and Islet Transplantation

Jonathan S. Fisher, Jonathan R. T. Lakey, and Christopher L. Marsh

Pancreas transplants are performed for the amelioration of insulin-requiring diabetes. Initially, pancreas transplants were performed only in those diabetic patients with chronic kidney disease who needed kidney transplants; these patients underwent simultaneous pancreas-kidney transplantation (SPK). Today, pancreas transplantation alone (PTA) or pancreas transplantation after living or cadaveric renal transplantation (pancreas-after-kidney [PAK] transplant) is increasingly common. SPK accounted for 72% of all pancreas transplants in 2010 (Fig. 110-1). There were approximately 3400 people in the United States waiting for pancreas transplants in 2013.[1] The 2011 Annual Report of the Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR) reveals that the number of new registrations as well as of pancreata recovered and transplanted in the United States steadily increased from 1997 to 2004, but there has been some decline since then.[2] Although there is less complete data for pancreas transplants outside the United States, the trends are similar with a decline in non-U.S. transplants performed since 2007. Several factors are thought to play a role. New insulin formulations and delivery systems in the form of insulin pumps have reduced the need for transplant in some patients. Selection criteria for potential recipients have become increasingly stringent as the average age of recipients has increased as well as the number of transplants being done in type 2 diabetic patients. Simultaneously, there has been a trend over time toward tighter donor criteria. Last, there have been recent downward trends in numbers of patients registered for pancreas transplants. New SPK registrations rose from 1412 in 1997 to a high of 2007 in 2000 and declined to 1671 in 2006. Some of this reduction may be the result of an increase in the number of patients receiving islet cell transplants. The relative roles of pancreas and islet cell transplantation remain controversial.

PATIENT SELECTION CRITERIA FOR PANCREAS OR ISLET TRANSPLANTATION

Indications for Transplantation

Indications for pancreas or islet transplantation include (1) insulin-dependent diabetes with associated diabetic complications (nephropathy, neuropathy, and retinopathy) and (2) diabetes with episodes of hypoglycemic unawareness.

A number of factors influence the choice between pancreas transplant and islet transplant. Because giving sufficient islets remains a limiting factor, islet transplants are more appropriate for patients with smaller insulin requirements, typically slender women. Larger patients (usually with higher insulin requirements) are more reliably served with whole-organ pancreas transplants. Islet transplantation is performed with a radiographic procedure and therefore is better suited for patients who cannot tolerate the surgical stress of whole-organ transplantation, such as older patients with severe coronary heart disease.

Pancreas or islet transplantations have not routinely been performed for type 2 diabetes mellitus because the primary defect in type 2 diabetes is insulin resistance, not insulin deficiency. There may be a role for pancreas transplantation in type 2 diabetic patients who develop islet failure after years of insulin resistance or those who have deficiencies in beta cell function such as maturity diabetes onset of the young (MODY, types 1 to 6) or mutations of the insulin receptor gene (e.g., type A insulin resistance or Rabson-Mendenhall syndrome).[3] A recent review of the United Network for Organ Sharing (UNOS) registry from 2000 to 2007 revealed that after adjustment for a variety of factors (e.g., age, race, weight, time on dialysis, cardiovascular disease), there were no differences in risk for death or kidney or pancreas failure according to diabetes classification.[4] The analysis suggested that insulin-requiring patients who have type 2 diabetes, are younger than age 50 years, and have a body mass index (BMI) below 30 kg/m^2 will become insulin independent with a pancreas transplant. The proportion of pancreas transplants that are performed in type 2 diabetics increased from 2% in 1995 to 7% in 2010.[5]

Most pancreas organs for transplantation come from deceased donors. However, one approach to increasing the donor supply has involved living donor laparoscopic distal pancreatectomy with or without simultaneous laparoscopic nephrectomy.[6]

Should living kidney donor recipients be offered a PAK transplant? An analysis of the UNOS database revealed no difference in survival of SPK recipients and living kidney donor recipients at up to 8 years of follow-up.[7] However, a European study showed an improved 10-year patient survival (83% in SPK versus 70% in kidney transplants alone) and noted a significantly lower progression of macrovascular disease (cerebrovascular, coronary, and peripheral vascular) with SPK transplants.[8] A review of the UNOS registry from 1997 to 2007 divided recipients with type 1 diabetes who received a living donor kidney transplant into two groups: (1) those who subsequently received a PAK transplant within a year of the kidney transplant (n = 1026) and (2) those who did not (n = 3528). At the end of the eighth year, the patients who subsequently received a PAK transplant had superior patient (85% versus 75%) and kidney graft survival (75% versus 62%).[9] Therefore the two-stage approach of PAK after a living donor kidney transplant should perhaps be offered to patients who have a living kidney donor and in whom the cardiovascular risk of the extended procedure required for SPK is considered too great.

The role of PTA in those with preserved renal function has recently been questioned. A single-center study of 131 PTA recipients revealed that PTA is an independent risk factor for the development of renal failure, presumably because of the nephrotoxicity of long-term immunosuppression.[10] An analysis of the UNOS database demonstrated worse survival for those with diabetes and preserved kidney function receiving a PTA than for those who remained on the waiting list and received conventional therapy.[11] The recent SRTR data reveal 1-year patient survival rates similar for PAK, SPK, and

Figure 110-1 Pancreas transplantation. PTA recipients (ranging from 95% to 97%). However, the 10-year patient survival rate was lowest for PAK recipients at 77% and similar for SPK and PTA recipients with rates of 82% and 71%. SPK resulted in the best pancreas graft survival rates, 86% at 1 year and 52% at 10 years. Graft survival rates for PAK and PTA recipients were slightly worse and similar to each other, with 1-year rates of 79% and 75%, respectively, and 10-year rates of 37% and 35%, respectively (Fig. 110-2).[1] Further close study is warranted, keeping in mind that a prospective, randomized trial of pancreas transplantation versus conservative therapy is not practical.

Medical Evaluation

The medical evaluation of the prospective pancreas transplant candidate is similar to that of the kidney-only recipient (see Chapter 102), although the cardiac workup is more extensive. The best candidates for transplantation are younger than 50 years and have a limited number of major complications of diabetes, such as hypoglycemic unawareness or diabetic neuropathy. Additional complications, such as vascular disease, orthostatic hypotension, and severe gastroparesis, put patients at higher risk of post-transplantation complications, but none of these factors by themselves exclude a patient from transplantation. Cardiovascular status is the primary deciding factor for transplantation eligibility because the surgery, infections, risk of thrombotic complications, and, until recently, rejection are more severe in the pancreas transplant recipient, demanding that the cardiovascular system be able to withstand multiple prolonged, hemodynamically stressful events. All patients require noninvasive cardiac stress evaluation because of the limited exercise capabilities of many patients. Cardiac catheterization is performed on the basis of the results of noninvasive testing or performed first for high-risk patients, typically those older than 45

years, those with diabetes duration of more than 25 years, smokers of more than 5 pack-years, and those with an abnormal electrocardiogram. Peripheral vascular disease is evaluated by clinical examination and by arterial duplex ultrasound. Patients with limb-threatening ischemia are typically poor pancreas transplant candidates. The medical evaluation for islet transplantation is similar to that for pancreas transplantation, but exclusion criteria are fewer because of lower surgical and inflammatory risks.

The last criteria for transplantation are that the donor and recipient match for ABO blood group and that the recipient sera are crossmatch negative against donor T cells by either the standard antiglobulin or flow cytometry crossmatch.

PANCREAS TRANSPLANTATION

Patient and Graft Survival

Pancreas graft survival rates have increased as a result of improved surgical techniques, donor selection criteria, and improvement in the composition of the preservation fluid, as well as more effective immunosuppressive regimens, despite an increasing proportion of high-risk patients.

There has been a trend toward tighter donor selection criteria. The ideal donor can be defined as 10 to 40 years of age, with a BMI

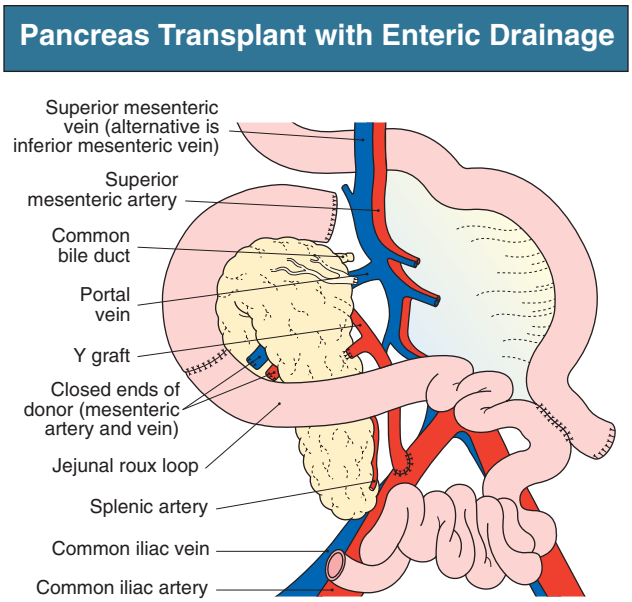

Figure 110-3 Pancreas transplant with enteric (portal) drainage.

less than 27.5 kg/m^2 and a cause of brain death that is other than cerebrovascular.[12] The UNOS database shows that over the past 5 years more than 60% of donors have had a cold ischemic time of less than 12 hours.[2]

The most commonly used cold storage solution is the University of Wisconsin (UW) solution, which has increased early pancreas graft function and reduced the occurrence of preservation pancreatitis. A second cold storage solution, histidine-tryptophan-ketoglutarate (HTK), offers the advantages of better tissue perfusion because of lower viscosity, less reperfusion hyperkalemia, and significantly lower cost. However, studies have suggested a higher incidence of graft pancreatitis and an increased rate of graft loss with HTK, particularly with longer cold ischemia.[13,14] Approaches using either a two-layer storage method with UW or an HTK solution and a second layer of highly oxygenated perfluorocarbon or the attachment of the pancreas to a low-pressure pulsatile perfusion system are being investigated.

The current gold standard immunosuppression for pancreas transplants is antibody induction therapy, tacrolimus, mycophenolate mofetil (MMF), and corticosteroids; this has led to a 40% decrease in incidence of rejection and an increase in 1-year graft survival to more than 90%. UNOS registry data show that human leukocyte antigen (HLA) matching has no effect on the outcome in SPK, whereas for PAK and PTA, a beneficial effect is seen by matching at the A and B loci. The reported 1-, 3-, and 5-year patient and graft survival rates with use of these techniques and criteria are shown in Figure 110-2.[1]

Enteric Drainage of the Pancreas Transplant

Current practice is to transplant the whole pancreas with a cuff of duodenum, which preserves the blood supply of the head of the pancreas and provides a means to drain exocrine secretions into either the small bowel (enteric drainage) or the bladder (Figs. 110-3 and 110-4).[1] From 2004 to 2008, the majority of the pancreas transplants in the United States were enterically drained (Fig. 110-5).[1] The graft may be placed in the right iliac fossa like a kidney, intraperitoneally, and vascularized from the common iliac vessels so that the secreted insulin enters the systemic circulation. The right side is

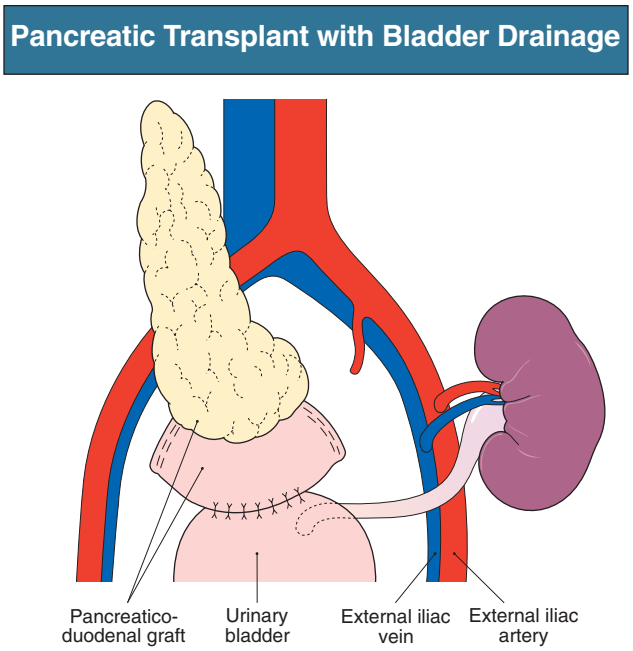

Figure 110-4 Pancreas transplant with bladder drainage. The pancreas may be placed in either the intraperitoneal or the extraperitoneal position.

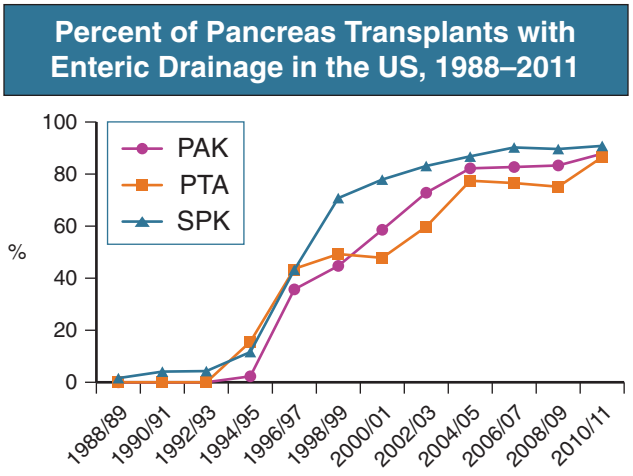

Figure 110-5 Percentage of U.S. primary pancreas transplantations with enteric drainage, by recipient category and era, 1988 to 2008. There has been a shift toward enterically drained compared with bladder-drained pancreas transplantation. *PAK,* Pancreas transplantation after living related or unrelated kidney transplantation; *PTA,* pancreas transplantation alone; *SPK,* simultaneous pancreas-kidney transplantation. *(Modified from reference 5.)*

preferred to the left because the vessels are somewhat more shallow on the right side and consequently the anastomoses are easier to perform. However, an alternative is to construct the venous anastomosis to the superior mesenteric vein, allowing more physiologic insulin output through the portal circulation. Currently, 15% to 20% of enterically drained transplants use portal drainage. In either approach, an interposition graft from the donor (typically a Y graft containing common iliac with external and internal branches) is used to provide inflow from the recipient common iliac artery to the graft superior mesenteric and splenic arteries. Some surgeons have advocated reconnection of the graft gastroduodenal artery if the

pancreaticoduodenal arcades are not intact. Pancreas transplants with venous outflow to the superior mesenteric vein can be placed either anterior to the small bowel mesentery or in a retroperitoneal position behind the ascending colon, where the superior mesenteric vein is reached from the side. Surgical outcomes have not differed whether the venous drainage is systemic or portal. Although portal drainage is considered more physiologic and avoids hyperinsulinemia, these apparent benefits are not well confirmed.

Immunosuppression

Most centers use antibody induction therapy during the first 1 to 2 weeks after transplantation. OKT3 has largely been replaced by antithymocyte globulin (ATG).[15] Other centers use an interleukin-2 receptor antagonist (basiliximab) or, most recently, an anti-CD25 antibody (alemtuzumab).[16,17] Antibody-mediated rejection may be more common than acute cellular rejection in patients receiving alemtuzumab.[18] Most centers use triple-drug maintenance immunosuppression with tacrolimus (or less commonly cyclosporine), MMF (or rarely azathioprine), and corticosteroids. There is increasing evidence of equivalent success with rapid corticosteroid elimination or corticosteroid avoidance protocols. Some centers replace the calcineurin inhibitor or MMF with sirolimus. With the more profound immunosuppressive induction produced by the newer antibodies (particularly alemtuzumab), there have been reports of immunosuppression protocols limited to a depleting antibody and a single additional agent.[17,19,20] Fortunately, cytomegalovirus (CMV) infection rates appear to be lower in corticosteroid-free regimens,[17] although there has been some increase in CMV infection in those receiving depleting antibody therapies.[16]

Graft Monitoring

The causes of pancreas graft dysfunction and the evaluation process are shown in Figure 110-6, Box 110-1, and Table 110-1.

During the immediate perioperative phase, intravenous insulin is used to decrease the stress on the transplanted pancreas by maintaining serum glucose concentration around 100 to 120 mg/dl (5.5 to 6.6 mmol/l). Serum glucose values are not an early marker of pancreas dysfunction; elevations are observed only after significant parenchymal pancreatic damage has occurred. With bladder

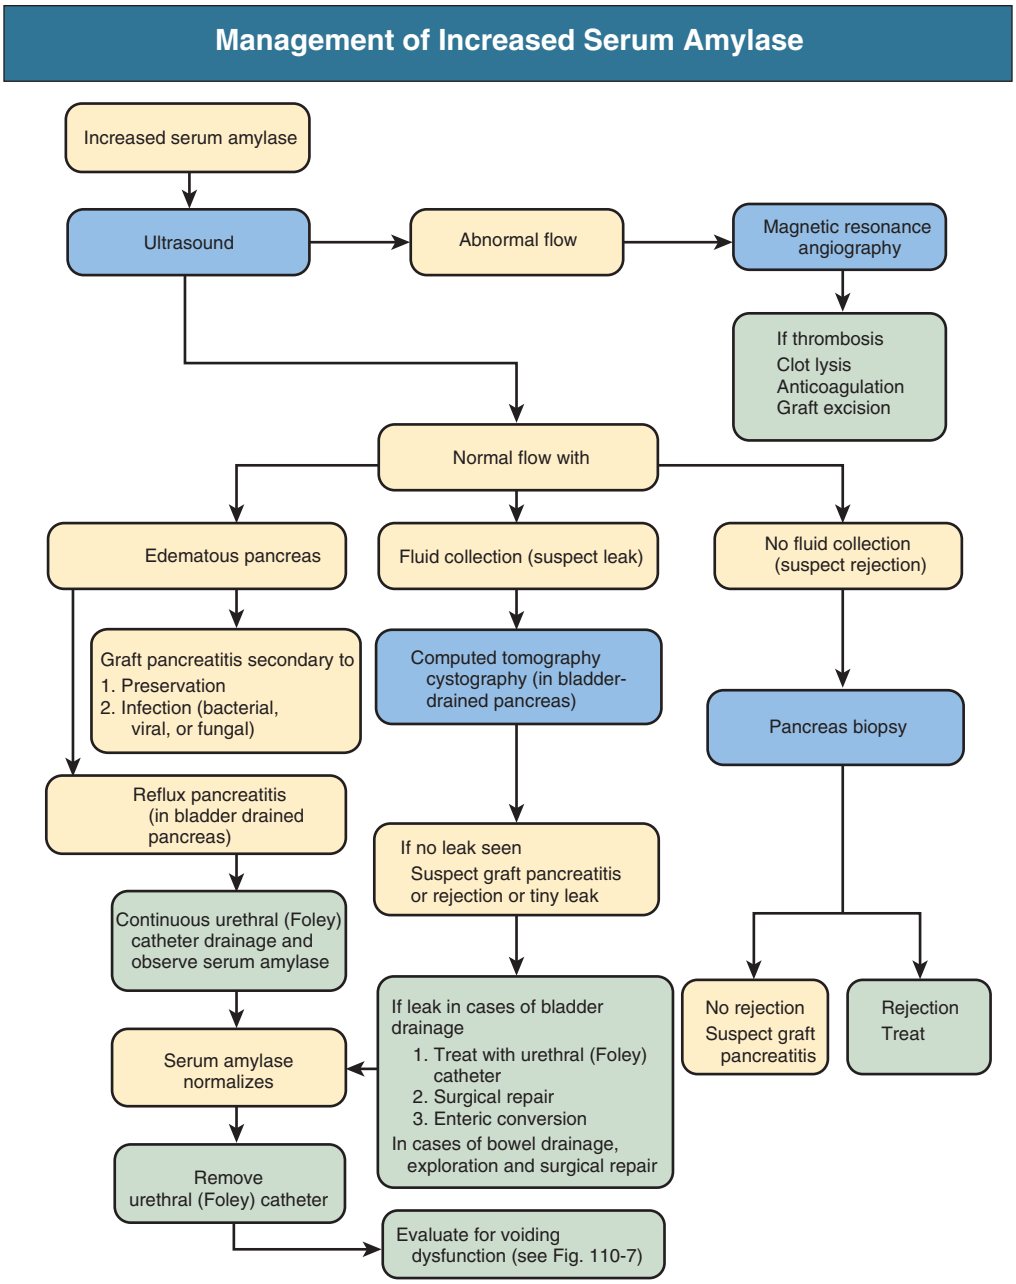

Figure 110-6 **Management of increased serum amylase after pancreas transplantation.**

drainage, urinary amylase excretion is measured on 12-hour collections and reported as units per hour. During the first 1 to 2 weeks after transplantation, serum amylase may be elevated as a result of pancreatic preservation injury. Trends are followed rather than absolute values, taking into consideration factors such as length of cold ischemic time and degree of organ edema. Stable serum levels are usually attained within 2 weeks after transplantation. Rising serum amylase or lipase concentration indicate possible graft injury, because both are moderately sensitive markers of pancreas rejection. However, other conventional causes of pancreatitis can still occur. Elevated fasting glucose and 2-hour postprandial glucose levels are relatively late indicators and only indicate dysfunction without revealing cause.

Ultrasound examination of the pancreas transplant is performed frequently in the early post-transplantation period to rule out vascular thrombosis. If the pancreas cannot be well visualized on

Evaluation of Pancreas Graft Dysfunction

Assessment	Tests
Laboratory tests	Serum amylase, blood glucose human anodal trypsinogen, cyclosporine or tacrolimus levels, C peptide In bladder-drained cases, urinary amylase and urine culture
Doppler ultrasound	Pancreatic blood flow, peripancreatic fluid collection, pancreatic ductal dilation In bladder-drained cases, evidence of bladder outlet obstruction
Computed tomography with or without cystography	Looking for leak and collections; this is performed by cystography in bladder-drained cases

Table 110-1 **Evaluation of pancreas graft dysfunction.**

ultrasound scan, magnetic resonance imaging and angiography may be informative. Any inflammatory state can also yield images of an edematous pancreas; however, other than for vascular thrombosis, imaging generally cannot reveal the cause of the dysfunction.

Biopsy of the pancreas transplant remains the gold standard for diagnosis of acute or chronic rejection. A biopsy may be performed at certain time points by protocol or at times of graft dysfunction to identify rejection or other causes of pancreatic injury before irreversible tissue damage has occurred. The easiest approach is a percutaneous biopsy with ultrasound or computed tomography guidance. The most frequent complication of percutaneous biopsy is a perigraft hematoma or transient hematuria, but rarely seen are pancreatitis, arteriovenous fistula, abdominal hemorrhage, bowel perforation requiring exploration, and even graft loss. Because of the risks associated with biopsy, if the clinical picture is consistent with a mild case of rejection, patients may be treated for rejection without biopsy confirmation.

Treatment of pancreas rejection is similar to that of kidney rejection and generally involves pulse intravenous corticosteroids or antilymphocyte antibodies (see Chapter 104).

Treatment response is achieved by following the return of serum amylase and lipase to baseline values. Imaging can be used to show resolution of edema and inflammation. Repeated biopsy, usually after a 2-week interval, is required to show resolution of more moderate or severe rejections and to look for histologic signs of the development of chronic rejection.

Patients with isolated pancreas rejection have an increased risk for kidney graft loss, supporting the concordance of acute rejection in the majority of patients.[21,22] In SPK or PAK patients, when biopsy of the pancreas cannot be performed safely, a kidney transplant biopsy may be used as a surrogate indicator. This must be done, however, in conjunction with serum tests because synchronous rejection occurs only 70% to 80% of the time.[23]

Antimicrobial Prophylaxis

Antimicrobial prophylaxis is much like that for a kidney transplant alone. Trimethoprim-sulfamethoxazole is prescribed for the prevention of urinary tract infections and *Pneumocystis* infection. Oral clotrimazole or nystatin is used for the prevention of oral candidiasis; some centers use fluconazole for prophylaxis of *Candida* urinary tract infections and intra-abdominal fungal or yeast infections. Oral acyclovir is given to patients with a history of herpes simplex infection and to patients who are CMV negative and receive CMV-negative donor organs. Otherwise, valganciclovir or ganciclovir is given for 3 months after transplantation to all patients who are CMV positive. Patients who are CMV negative who receive CMV-positive organs are often treated for 6 months. Patients treated for rejection are typically returned to any discontinued anti-infectious prophylaxis for 1 to 3 months after rejection therapy.

Metabolic Monitoring

In addition to monitoring of the serum and urinary concentrations of amylase and the serum concentration of lipase, serum creatinine, potassium, magnesium, and bicarbonate levels must be monitored. Magnesium wasting is common with calcineurin inhibitors and frequently requires oral supplementation.

Surgical Complications

Surgical complications of pancreas transplantation are shown in Table 110-2. Superficial infections and deep-seated abscesses are commonly fungal. The source of fungal contamination is thought to be the duodenal segment. Therefore, topical antibiotic and antifungal solutions are used to irrigate the donor duodenum during procurement and implantation. Patients commonly receive 24 to 48 hours of postoperative antibiotics and fluconazole.

The causes of wound drainage are seroma, lymphocele, pancreatic fistula from either the tail or the anastomosis to the bladder or bowel, wound dehiscence, and preservation pancreatitis. Preservation pancreatitis may lead to wound drainage of whitish yellow, thick, noninfectious material formed from the enzymatic digestion of tissue, leading to fat necrosis and saponification. Wound drainage is seen more often with the extraperitoneal placement of the pancreas and also occurs when a pancreas from an obese donor is used. It is also associated with a mild increase in serum amylase concentration and variable changes in the serum glucose concentration.

Vascular complications occur in about 5% of patients and include arteriovenous fistulas from surgery or biopsy, venous and arterial

Surgical Complications After Pancreas Transplantation

Type of Complication	Presentation	Diagnostic Findings and Testing	Treatment Options
Abscess	Fever, erythema of wound, wound drainage	Elevated white blood cell (WBC) count, fluid collection on computed tomography (CT) scan, pus on aspiration	Open or percutaneous drainage
Graft pancreatitis	Pain over allograft, lower abdominal pain	Elevated serum amylase, enlarged pancreas allograft	Octreotide or somatostatin Urethral (Foley) catheter if bladder drained
Lymphocele	Mass on palpation, urgency if bladder compression	Fluid collection on CT scan, clear fluid on aspiration	Open or percutaneous drainage
Wound drainage	Pancreatic debris, no erythema	Culture, CT scan to rule out deep abscess	Local wound care
Dehiscence	Wound open		Wound care, surgical closure
Arteriovenous fistula	Hematuria, abdominal bleeding	Doppler ultrasound, angiography	Embolization, surgical repair
Graft thrombosis	Elevated blood sugar Bloody urine if bladder drained	Low serum and urine amylase, sepsis-like syndrome, ultrasound or magnetic resonance imaging	If partial, thrombolytic therapy or anticoagulation (high risk of bleeding), graft pancreatectomy
Pancreatic fistula or leak (bowel drained)	Pain over allograft, sepsis, peritonitis, fever	Elevated WBCs, fluid collection on CT scan	Surgical drainage and repair

Table 110-2 Surgical complications after pancreas transplantation.

thrombosis, and rarely mycotic aneurysms. The pancreas is a low–blood flow organ; vascular thrombosis rates were previously as high as 10%, but current rates are below 5%. Means of reducing the rate of thrombosis include minimization of warm and cold ischemia, procurement procedures involving a no-touch technique with use of the duodenum and spleen as handles, and postoperative antiplatelet activity with aspirin. In procedures involving longer cold ischemia times, a more edematous graft, or concern about low inflow or outflow, intravenous heparin is sometimes used for the first few postoperative days. Partial thrombosis may resolve with thrombolytic therapy or anticoagulation. More extensive thrombosis requires urgent surgical intervention. Complete graft thrombosis, especially in the immediate postoperative period, mandates urgent graft removal to prevent sepsis syndrome or a more diffuse hypercoagulable state, leading to further vascular thrombotic complications such as myocardial infarction.

Nonsurgical Complications

Nausea and vomiting are common, and causes include gastroparesis, constipation, cholelithiasis or esophageal reflux developing from motility problems, and esophagitis with or without CMV disease. Antiemetics plus histamine H_2 blockers or proton pump inhibitors are usually effective therapy and are given for 2 to 3 months after transplantation. Persistent symptoms may require prokinetic agents (metoclopramide or erythromycin). Diarrhea can be caused by immunosuppressive medications, intrinsic gut motility problems, food intolerance, or CMV or other infection. Constipation is treated with increased fluid intake, dietary modification, increased activity, and a regular low-dose schedule of stool softeners or laxatives.

Orthostatic hypotension may worsen after transplantation as a consequence of prolonged bed rest in the presence of diabetic autonomic neuropathy. Treatment may include a salt-loading diet, with a mineralocorticoid (fludrocortisone) or an α-adrenergic agonist (midodrine).[23]

Bladder Drainage of the Pancreas Transplant

In the early days of pancreas transplantation, with less effective immunosuppression and before the era of real-time ultrasound and percutaneous biopsy, the exocrine secretions from pancreas transplants were more commonly drained through an anastomosis of the donor duodenum to the recipient's bladder. This manner of drainage allows monitoring for rejection by measurement of urinary amylase and also avoids enterotomy-associated risks of infection and leakage. Cystoscopic biopsy through the duodenal cuff is used in bladder-drained transplants.[24] The disadvantages of bladder drainage include susceptibility to dehydration, metabolic acidosis, and frequent urologic complications. Primary enteric drainage avoids these complications and is more physiologic but does not allow urinary amylase monitoring. With improved surgical techniques, increased use of real-time ultrasound, and percutaneous needle biopsy, the outcomes of enteric drainage now match those of bladder drainage.

Current Indications

Bladder drainage is still appropriate when there is a history of major abdominal surgery, in the presence of Crohn disease or other small bowel disease, and for older patients with less cardiovascular reserve, in whom a laparotomy may be avoided through a smaller lower quadrant retroperitoneal incision similar to that for a kidney transplant.

Metabolic Complications

With bladder drainage there is high urinary loss of bicarbonate in pancreatic exocrine secretions, which may require as much as 130 mmol/day of replacement. Without replacement, patients develop metabolic acidosis with nausea and vomiting, which may lead to volume depletion, hypotension (exacerbated by underlying autonomic neuropathy), and graft thrombosis. Oral sodium bicarbonate, typically 2 g four times daily, is needed. Fluid intake should be 2.5 to 3 l/day to accommodate pancreatic and renal fluid outputs. This intake may be difficult to achieve because abdominal bloating from diabetic gastroparesis is exacerbated by the large fluid intake and the gas released from sodium bicarbonate tablets. Patients who are unable to maintain adequate oral intake may require intravenous fluids including sodium bicarbonate. In patients who require intravenous repletion for longer than 1 month, consideration should be given to placement of a tunneled venous catheter or a buried central venous port for fluid administration.

Urologic Complications

Urologic complications are common after bladder drainage (Table 110-3).[25] Pretransplantation bladder dysfunction resulting from diabetic autonomic neuropathy causes a large-capacity bladder, decreased bladder sensation, increased residual urine volume, and decreased urinary flow rates. Bladder function is worsened by the autoaugmentation of the bladder by the added duodenal segment. Preoperative urodynamics are abnormal in up to 43% of patients but are not predictive of post-transplantation urologic complications such as reflux pancreatitis or infections.[26]

Urinalysis is difficult to interpret with the bladder-drained pancreas. The urine contains white cells from duodenal mucosal sloughing and may be leukocyte esterase positive without bacteriuria. Urine protein excretion is elevated to 1 to 3 g/day in most patients, composed of pancreatic enzymes, immunoglobulins, other globulins, albumin, and digested fragments of these proteins. Urinary albumin, if it is measurable in the presence of enzymatic degradation, may come from the transplanted or native kidneys.

Macrohematuria occurs in up to 28% of bladder-drained pancreas recipients. Early hematuria is related to surgical trauma to the bladder or duodenal mucosa near the cystoduodenostomy site and usually clears with diuresis or bladder irrigation.[24] Continuous bladder irrigation requires caution because the cystoduodenostomy is vulnerable to rupture if the drainage catheter becomes obstructed. Late hematuria, beyond 2 to 4 weeks after transplantation, can arise from anastomotic bleeding, duodenal mucosal sloughing or ulceration, reflux pancreatitis, cystitis, graft thrombosis, rarely arteriovenous fistulas, and pseudoaneurysms. Evaluation should include ultrasound, urine culture, and cystoscopy. If the pancreas appears to be the source on cystoscopy, biopsy of the pancreas may be required to determine the exact cause.

Microhematuria should be evaluated. Evidence is sought for recurrent disease, new renal disease, or genitourinary malignant neoplasms.

Urinary Tract Infections

Risk factors for urinary tract infection after pancreas transplantation include large bladder capacity, incomplete bladder emptying, high bladder urine pH (from pancreatic bicarbonate), bladder and urethral mucosal irritation from activated pancreatic enzymes with the loss of mucosal barrier, prolonged bladder catheterization, and immunosuppression.[27] Most centers administer oral antibacterial and antifungal prophylaxis for up to 6 to 12 months or indefinitely after transplantation.

Urologic Complications of Bladder-Drained Pancreas Transplants				
Complication	**Cause**	**Presentation**	**Evaluation**	**Treatment Options**
Urinary tract infection (UTI)	Diabetic bladder dysfunction (DBD)	Asymptomatic, or dysuria, fever, sepsis	Urine culture; check postvoid residual, if elevated urodynamics	Culture-specified antibiotics, prophylactic antibiotics Female: double and timed voiding, clean intermittent catheterization (CIC) Male: α-adrenoceptor blockers to aid bladder emptying, CIC, bladder neck–prostate incision If treatment failure, enteric conversion: Foley catheter drainage
Reflux pancreatitis	DBD	Asymptomatic or pain over pancreas allograft, elevated serum amylase	Check serum amylase, computed tomography (CT) cystogram to exclude leak or duct obstruction	If DBD: double and timed voiding, CIC, α-blockers to aid bladder emptying If multiple and symptomatic episodes: bladder neck–prostate incision or enteric diversion
Duodenal cystotomy leak	Ischemic injury to duodenal cuff, cytomegalovirus or other infection, rejection, DBD	Pain over allograft, or peritonitis, elevated serum amylase	Check serum amylase, elevated creatinine, leak on CT cystogram	Foley catheter drainage, if small If early, open surgical repair with resection and closure of layers, evaluate for DBD after recovery If late, consider enteric conversion
Urethritis or dysuria syndrome, occasional urethral disruption	UTI or DBD causing activation of pancreatic enzymes with digestion of urethral mucosa	Dysuria, urinary retention, hematuria	Check postvoid residual, low-grade UTI; after recovery, evaluate for DBD	Foley catheter, analgesics, empiric treatment of UTI If multiple and symptomatic: enteric conversion

Table 110-3 **Urologic complications of bladder-drained pancreas transplants.**

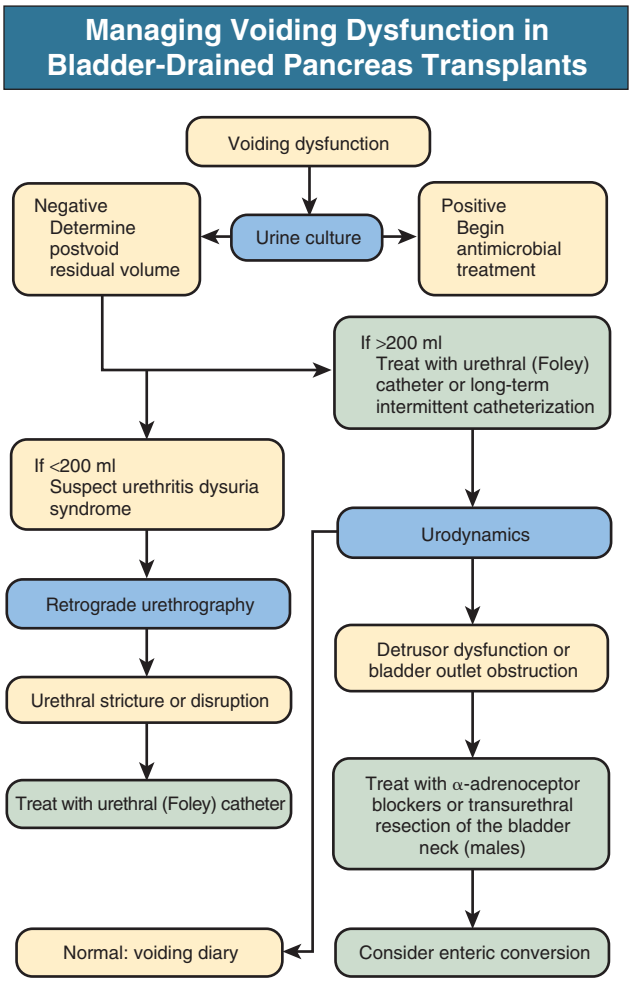

Figure 110-7 **Management of post-transplantation voiding abnormalities.** *(From reference 25.)*

Urinary reflux pancreatitis, which causes pancreas graft dysfunction, may be associated with perigraft abdominal pain and fever. It is often a result of poor bladder function and requires drainage with a bladder catheter for 5 to 7 days and assessment of bladder dysfunction (Fig. 110-7).

A urethritis dysuria syndrome occurs in 2% to 8% of pancreas recipients with bladder drainage and is caused by uroepithelial exposure to the activated pancreatic proenzymes trypsinogen, chymotrypsinogen, and procarboxypeptidase. Pancreatic exocrine secretions consist of bicarbonate, amylase, lipase, and proenzymes, which are activated by the enterokinase in the graft duodenal brush border. Increased intravesical enzyme activation occurs with low-grade urinary infections and urinary stasis, and patients will develop voiding pain or penile, glandular, meatal, or vulval ulceration. Enzyme activation may be minimized by treatment of low-count bacteriuria, increase in fluid intake, and frequent voiding. If emptying does not improve with α-blockers, continuous Foley catheter drainage for 7 to 10 days has been effective.

Enteric Conversion

Enteric conversion is an option for most of the chronic urologic complications associated with bladder-drained pancreas transplantation. The indications are urethral disruption, recurrent urine leak, persistent bleeding, chronic urinary tract infection, dysuria, recurrent hypovolemia, and metabolic acidosis. The conversion rate varies from 8% to 14%. It is ideal to wait until 6 to 12 months after transplantation, when possible, to allow monitoring of urine amylase for early rejection episodes.

Late Complications

Late complications after pancreas transplantation typically fit into one of two patterns. There can be an acute presentation of graft rejection, not different from that seen in early graft dysfunction. The second pattern is more insidious; chronic inflammatory states from

chronic rejection, ischemia, or infection may lead to gradual graft loss. Unfortunately, there is no practical test to measure small decrements in graft function in the way serum creatinine allows detection of kidney transplant dysfunction. Although it is lacking the necessary sensitivity, patients are typically asked to measure 2-hour postprandial glucose levels (which are more sensitive than fasting blood glucose levels) weekly and to report trends or sudden increases to the physician.

IMPACT OF PANCREAS TRANSPLANTATION ON DIABETIC COMPLICATIONS

Pancreas transplantation is performed to eliminate the need for exogenous insulin and the risk of severe hypoglycemic episodes and to stop or to reverse the consequences of hyperglycemia. Well-functioning pancreas transplants result in normal fasting blood glucose concentrations, normal glycated hemoglobin levels, and only slightly abnormal oral glucose tolerance testing results.[28]

Hypoglycemia

Although severe hypoglycemia is rare, mild hypoglycemia may develop in patients with a well-functioning pancreas graft once low baseline immunosuppression has been reached, especially in those patients who have regained little weight after transplantation and who are physically active. Postprandial hypoglycemic episodes are not always symptomatic. They are associated with high-carbohydrate meals, excessive intake of caffeine or alcohol, excessive exercise, and, in some patients with hypoglycemia, circulating anti-insulin antibodies. This is not often a significant clinical problem and is usually resolved by avoidance of carbohydrate-rich meals.

A major benefit of pancreas transplantation is restoration of glucagon secretory responses to hypoglycemia. In type 1 diabetics, the absence of functional beta cells within the islet eliminates the normal physiologic response by which intra-islet insulin tonically dampens secretion of glucagon from alpha cells. Consequently, diabetic patients are usually at risk of prolonged hypoglycemia secondary to injected insulin because there is failure of the normal counterregulatory action of glucagon on the liver to increase glycogenolysis. Despite the fact that the transplanted pancreas is placed ectopically and does not develop vagal control, the transplanted organ has normal glucagon responses to insulin-induced hypoglycemia and resultant counterregulation of hypoglycemia through increased hepatic glucose production. After pancreas transplantation, hypoglycemic awareness returns, as well as partial return of defective epinephrine secretion during insulin-induced hypoglycemia.

Hyperglycemia

Post-transplantation hyperglycemia may be caused by pancreas graft dysfunction, inadequate insulin release secondary to high tacrolimus or occasionally cyclosporine levels, resistance to insulin secondary to corticosteroids, weight gain, and inadequate physical activity. Although the use of tacrolimus has reduced pancreas graft rejection, it also decreases insulin gene transcription. If laboratory and imaging evaluations (see Table 110-1) are normal, hyperglycemia is the result of decreased insulin production or else of peripheral insulin resistance, which can be identified by measurement of glucose usage rates and glucose/arginine-potentiated insulin secretion. In the absence of graft rejection, post-transplantation hyperglycemia should first be managed by dietary intervention and exercise. Insulin may be needed initially but can often be discontinued as oral hypoglycemic agents begin to take effect. Sulfonylureas are effective therapy. Hyperglycemia secondary to rejection is a late event and indicates irreversible graft damage. Because of the increased risk of rejection with manipulation of immunosuppression, minimizing the tacrolimus dose or changing to cyclosporine or sirolimus should not usually be considered until these measures have failed.

Microvascular Complications

Retinopathy

In a prospective fundoscopic study of SPK patients during 45 months, there was a decreased need for post-transplantation laser therapy, and the diabetic retinopathy showed stabilization in 62%, improvement in 21%, and progression in 17%.[29] In the postoperative period, patients may develop neoproliferation and retinal hemorrhages if preoperative blood glucose control is very poor and blood glucose normalizes rapidly after transplantation. Patients remain at risk of retinal detachment because of scarring secondary to previous retinal damage. Cataracts are more common after transplantation.

Neuropathy

Sensory and motor nerve conduction velocities improve rapidly after pancreas transplantation and then stabilize.[30] Greater recovery is seen in nonobese, younger, shorter patients; in those with better initial action potential amplitudes; in those not receiving renal replacement therapy; and possibly in those receiving angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.[31] The recovery of action potential amplitudes is gradual, with continuing improvement up to 5 years beyond transplantation. Recovery is more complete in sensory than in motor nerves.

There is greater improvement in autonomic reactivity and gastric emptying in SPK recipients compared with diabetic kidney-only transplant recipients.[32] If autonomic symptoms are severe at the time of pancreas transplantation, improvement is unlikely.

Nephropathy

Early diabetic nephropathy is characterized by increased glomerular basement membrane thickness and an increase in mesangial volume. Renal transplant biopsy specimens from diabetics with SPK and kidney-only transplants within 2.5 years of transplantation show glomerular basement membrane thickness within the normal range. After 2.5 years from transplantation, 92% of renal biopsy specimens from the kidney-pancreas recipients have a normal glomerular basement membrane thickness compared with only 35% of the biopsy samples from the kidney-only recipients; relative mesangial volume was normal in 82% of the biopsy specimens from kidney-pancreas recipients compared with only 12% in the kidney-only recipients.[27] Thus, concurrent pancreas transplantation decreases the occurrence of the changes of diabetic nephropathy that may result in allograft loss.[33]

Vascular Disease

Successful kidney-pancreas transplantation results in a significant improvement in the control of hypertension compared with kidney transplant alone in type 1 diabetics.[34] Increase in peripheral vascular disease has been reported in kidney-pancreas transplant recipients compared with kidney-alone transplant recipients[35]; however, another study found the same prevalence of peripheral vascular disease after pancreas transplantation as occurred in diabetic kidney-only recipients who refused pancreas transplantation for nonmedical reasons and in nondiabetic kidney transplant recipients.[36] It is encouraging to note that one study showed that after a 10-year mean

observation period, the progression of macrovascular diseases (cerebrovascular, coronary, and peripheral vascular) was significantly lower in recipients with a functioning SPK compared with a kidney transplant alone.[8]

A study using intravital microscopic evaluation of nail bed and conjunctival vasculature found improved vascularization (as assessed by a reduction in venular diameter, increased number of arterioles per unit area, and elevation of the perfusion capacity) only in kidney-pancreas recipients.[37]

Quality of Life and Social Issues

Pancreas transplantation is a very stressful event and can tax even the strongest of family relationships. Pretransplantation debilities (decreased vision, neuropathy, muscle weakness, orthostatic symptoms) can be exacerbated by the surgery and immunosuppressive medications. Patients who smoke or drink alcohol and are without family support do not survive as long after transplantation. However, kidney-pancreas transplant recipients with social support and well-functioning grafts report an increased global quality of life and frequently return to work, although the number returning to work is not much different from those receiving a kidney transplant alone.[38] In living donor SPK, preliminary results suggest a maintained level of quality of life for donors and improvement for recipients.[39]

Pregnancy After Pancreas Transplantation

Within 1 year of transplantation, menstruation and ovulation return in most women of childbearing age. The U.S. National Transplantation Pregnancy Registry has reported 62 pregnancies in 40 SPK patients.[40] The outcomes were 50 live births, three therapeutic and 10 spontaneous abortions (one twin reduction), and one ectopic twin pregnancy. The newborn outcomes were prematurity (39 of 50), low birth weight (32 of 50), other neonatal complications (28 of 50), and neonatal death (1 of 50). Ten patients had rejections that resulted in grafts loss, and 58% of the patients required cesarean section. Hypertension, prematurity, preeclampsia, and growth retardation frequently complicated the pregnancies, even with good renal function. Gestational diabetes appeared in 3%.

All transplant recipient pregnancies require high-risk obstetric care. Consensus opinion is that pregnancy is safe by 1 year after transplantation under the following conditions: no rejection has occurred in the past year, graft function is stable, no active infections that could have a negative impact on the fetus (e.g., CMV infection) are present, and the patient is not taking any teratogenic medications.[41] MMF has been linked to structural malformations, and patients planning on conception should transition to another agent 6 weeks before trying to conceive.[42] Cyclosporine and tacrolimus levels often decline during pregnancy and require close monitoring to prevent rejection. Cesarean section is not mandatory; vaginal deliveries, however, must be observed for signs of allograft duodenal rupture. The average gestational period is 35 ± 2 weeks; the average birth weight is 2150 ± 680 g. There is no evidence that the children of transplant recipients are more likely to have abnormal development.

The management of other medical issues does not differ from that in kidney-only transplant recipients (see Chapters 101 and 102).

ISLET TRANSPLANTATION

Islet transplantation, with its reduced antigen load, technical simplicity, and low morbidity, has the potential to dramatically improve the quality of life of individuals with type 1 diabetes. The first series of islet allotransplantations in type 1 diabetic patients were reported in 1977.[43] There were sporadic reports in the 1990s of insulin independence for extended periods after islet allotransplantation.[44,45] Autotransplantation studies then demonstrated that a critical mass of 300,000 IE (islet equivalents) could reestablish and maintain insulin independence beyond 2 years.[46] To date, the longest period of insulin independence after autotransplantation is more than 16 years.[47]

Islet After Kidney Transplantation

The initial allogeneic islet transplants in patients with type 1 diabetes were performed in the 1980s and 1990s in patients with end-stage renal disease as sequential islet after kidney (IAK) or simultaneous islet-kidney transplantation. Because the kidney transplant patients were already immunosuppressed, the IAK transplant procedure carried a minimal risk. However, there could be destabilization of the transplanted kidney and also islet dysfunction because most kidney transplant immunosuppression protocols included corticosteroids. Nevertheless, there were beneficial effects from improved glycemic control on both survival and function of transplanted kidneys.[48] Metabolic control (hemoglobin A_{1c} [HbA_{1c}] level and fasting glycemia) improved after IAK transplantation even in patients receiving low-dose corticosteroids. Adverse events included procedure-related pleural effusion and cholecystitis.[49]

Of the 237 well-documented allotransplants recorded in the Collaborative Islet Transplant Registry (CITR) from 1990 to 2000, less than 12% of recipients were insulin free at 1 year after transplantation. The reasons for this failure rate may include subtherapeutic islet implant mass, high rate of engraftment failure, islet damage in the liver (the site of implantation) by direct local toxic effects of the immunosuppressants, ineffective immunosuppression that fails to prevent rejection, recurrent autoimmune diabetes, and islet functional exhaustion. Four criteria were associated with insulin independence: (1) an islet implant mass of more than 6000 IE/kg, (2) a cold ischemia (preservation) time of less than 8 hours, (3) β-induction therapy with polyclonal antibodies such as antilymphocyte globulin or thymoglobulin (ATG), and (4) the liver as the favored implantation site. Early immunosuppressive regimens were relatively ineffective in preventing allograft rejection compared with their effect on vascularized pancreas grafts. Most if not all immunosuppressive agents were associated with impaired beta cell function and reduced graft revascularization.

By the end of 2009 there had been 571 allogeneic islet transplant recipients, both islet transplant alone (ITA), and IAK or simultaneous islet-kidney (SIK) transplantation. Overall achievement of insulin independence was 65% in the first year after islet infusion (with or without reinfusion), and by year 2 this rate increased to 75%.

More success with insulin independence was reported in nonuremic type 1 diabetics transplanted with an average of 800,000 islets by use of the Edmonton protocol, a corticosteroid-free immunosuppression regimen of daclizumab, sirolimus, and low-dose tacrolimus. Although follow-up of this cohort has since confirmed long-term C-peptide production with therapy that is safe and well tolerated, insulin independence is maintained in only a minority.[49] There has since been an exponential increase in clinical islet transplant activity; more patients with type 1 diabetes have now received islet transplants in the past 5 years than in the entire preceding 30-year history of islet transplantation.

Partial graft function, such as improvement of fasting C-peptide alone (to 0.3 to 0.5 ng/ml) combined with exogenous insulin, is sufficient to be associated with improved HbA_{1c}, glycemic control, and

(Modified from reference 50.)*

lower levels of severe hypoglycemia. The results are improved with higher fasting C-peptide level.

Technique of Islet Transplantation

The current technique of islet transplantation involves deceased donor pancreas procurement, organ preservation, enzymatic isolation of the islets, purification, and percutaneous injection of sterile islets into the liver through the portal vein via a catheter placed under radiographic guidance (Fig. 110-8).[50] Although accessing of the portal vein percutaneously is relatively invasive, the entire procedure can be performed on an outpatient basis. Effective mechanical and physical methods to seal the catheter track reduce the risk of postprocedural bleeding.[51] Bleeding related to the procedure (23%), thrombus in segmental branches of the portal vein (8%), and punctured gallbladder (3%) are the most observed acute complications after islet transplantation.[52]

There is still a need for greater availability of transplantable islets as well as for improvement in islet engraftment and preservation. Although previous reports indicate that the two-layer method for pancreas preservation improves islet isolation outcome, our recent data show no beneficial effect of the two-layer method on islet isolation and transplantation outcomes.[51] Islet culture for 24 to 48 hours in antioxidant-enriched medium has improved the quality of islet preparations and facilitated the shipment of islets between centers.[52]

Medical Complications

There are also complications of islet transplantation that are not directly related to the procedure itself.[48] Changes consistent with fatty liver are reported in 22% of patients who had magnetic resonance imaging after transplantation. Mouth ulcers occur in 90% of patients and usually respond to simple antiseptic measures or topical triamcinolone ointment together with a reduction in the dose of sirolimus. Diarrhea (60%) and acne (52%) are frequent. Forty-three percent of recipients complained of edema, severe enough in 12% to necessitate a change in the immunosuppressive regimen. Weight loss is common.

In 27 of the 571 islet recipients in CITR, 29 incidents of neoplasm was diagnosed. Of these incidents, 21 (72%) were benign and 6 were malignant.

Glycemic Control and Insulin Independence

Successful islet transplantation establishes normal HbA_{1c} levels, although the fasting glucose concentration tends to be slightly elevated and there is often impaired glucose tolerance. Another

difference between successful pancreas and islet transplants is that placement of islets within the liver results in failure of the beta cell response to hypoglycemia, even though there is responsiveness to intravenous arginine. In a recent analysis, 82% of 118 islet recipients in three North American centers were insulin free at 1 year.[52] However, in a 5-year follow-up in Edmonton,[45] only 7.5% maintained insulin independence, although 82% had detectable C-peptide (Fig. 110-9). The median duration of insulin independence was 15 months.

From 1997 to 2002, the insulin-independence rate at 1 year after islet transplant was 51%, decreasing to 18% by 5 years after transplant. Improvements in islet isolation and transplant procedures have improved the insulin-independence rate, to 66% by 1 year and 44% by 3 years after transplant for procedures performed in 2007 to 2010 (Fig. 110-10).[53]

Durability of islet graft function was found to have improved significantly when islet transplants from 1999 to 2003 were compared with those from 2004 to 2007, with 1- and 5-year fasting C-peptide of 0.3 ng/ml or higher of 74% and 35%, compared with 78% and 43%, respectively (see Fig. 110-10).[52]

Immunosuppressive Regimens

Tacrolimus, cyclosporine, and corticosteroids are diabetogenic through increased peripheral insulin resistance or by direct islet cell toxicity. Oral administration increases portal venous drug

concentrations and the possibility of significant injury to intrahepatic islet grafts. Most programs use corticosteroid-free and calcineurin inhibitor–sparing protocols for islet or kidney recipients with different combinations of MMF and sirolimus. MMF reduces early pancreas rejection rates. Insulin independence has now been achieved with islet grafts derived from non–heart-beating donors and after sequential kidney-islet transplantations using sirolimus-based therapy. Islet engraftment can also be improved with use of a calcineurin inhibitor–free regimen with profound T cell depletion.[48] Anti–T cell therapy using ATG or OKT3 may be associated with a cytokine storm, which is toxic to islets, and newer induction agents (anti–interleukin-2 receptor blockers) may be particularly useful to minimize cytokine release.

A number of new immunosuppressive agents that offer the potential for more islet-friendly approaches are now entering clinical trials. These include combinations of biologic agents, such as ATG, rituximab, and alemtuzumab; novel anti–T cell biologic agents, some of which offer the prospect of inducing tolerance based on animal studies; and agents that produce costimulatory blockade.

Based on CITR data, the highest 5-year insulin-independence rates after transplant, 60% to 70%, were seen with a combination of T cell depletion and tumor necrosis factor (TNF) antagonism, and a maintenance combination that included calcineurin and inosine monophosphate dehydrogenase (IMPDH) inhibitors. This regimen was in use starting in the 2004 to 2006 era of islet transplantation, leading to improved 1- and 3-year insulin-independence rates (see Fig. 110-10).[54]

CHAPTER 111

Kidney Disease in Liver, Cardiac, Lung, and Hematopoietic Cell Transplantation

Colm C. Magee

It is now well recognized that kidney disease can complicate all forms of solid organ nonrenal transplantation.[1-3] Kidney disease can occur in the immediate pretransplantation period, in the early postoperative period, or during the long term. In general, it is associated with longer hospitalization, higher morbidity, higher mortality, and greater expense. Although there are organ-specific factors (such as the high prevalence of hepatitis C virus infection in liver transplant recipients) that have an impact on the incidence and severity of kidney disease, some useful generalizations can be made.

GENERIC ISSUES OF KIDNEY DISEASE IN NONRENAL SOLID ORGAN TRANSPLANTATION

Use of Serum Creatinine and Derived Equations to Measure Glomerular Filtration Rate

Transplant candidates and recipients often have low muscle mass and low creatinine generation. Hence, a mildly elevated serum creatinine concentration may hide severe kidney disease. This is particularly relevant in the pretransplant patient with liver failure.[3,4] Such patients should have glomerular filtration rate (GFR) estimated by creatinine clearance (which will tend to overestimate) or preferably by iothalamate clearance (where it is available). Of the various serum creatinine–based equations to estimate GFR, the Modification of Diet in Renal Disease (MDRD) equation appears to correlate best with true post-transplantation GFR; however, even this equation has limited accuracy in all forms of solid organ transplantation.[4]

Nephrotoxicity of Calcineurin Inhibitors

The introduction of the calcineurin inhibitor (CNI) cyclosporine in the 1980s revolutionized the field of organ transplantation, and the CNIs cyclosporine and tacrolimus remain a cornerstone of immunosuppression in recipients of nonrenal allografts.[1] However, there is little doubt that CNIs contribute significantly to both acute kidney injury (AKI) and chronic kidney disease (CKD) in these recipients. There is speculation that CNI nephrotoxicity is more severe in nonrenal than in renal transplantation because (1) dosage and blood concentrations of CNIs tend to be higher in nonrenal transplantation and (2) the lack of normal innervation of the transplanted kidney may protect it from early CNI injury. CNIs also exacerbate post-transplantation hypertension and diabetes mellitus, which cause renal damage in the long term.

Acute CNI nephrotoxicity is thought to be mainly a pre-renal syndrome caused by vasoconstriction of the afferent glomerular arteriole (see also Chapter 101). Tubular damage and microvascular disease may occur in more severe cases. In the early post-transplantation period, AKI is usually multifactorial, and it is difficult to quantify the degree to which CNI toxicity is contributing to the problem. In practice, doses of CNIs are often temporarily reduced in the setting of AKI. Acute CNI-induced thrombotic microangiopathy (TMA) is rare in nonrenal transplant recipients. Chronic CNI nephrotoxicity is probably a result of prolonged renal ischemia and other effects, such as direct stimulation of renal fibrogenesis. Typically the patient is hypertensive (CNIs worsen hypertension) and there is a steady fall in GFR, most marked in the first 6 to 12 months after transplantation (Fig. 111-1).[5] Dipstick urinalysis shows minimal or no hematuria and minimal or mild proteinuria. Urine protein-creatinine ratio or 24-hour urine collections confirm low-grade proteinuria. Renal histology shows interstitial fibrosis, arteriolar hyalinosis, arteriosclerosis, and secondary focal glomerulosclerosis.[6] There may also be features of chronic TMA.[6] In practice, renal biopsies are rarely performed unless there are clinical features suggestive of a renal disorder other than CNI toxicity.

It is not surprising that the presumed high prevalence of chronic CNI nephrotoxicity has generated interest in low-dose or zero-dose CNI protocols. Just as in renal transplantation, these typically involve use of mycophenolate mofetil (MMF) or mammalian target of rapamycin (mTOR) inhibitors.[1,3,7] However, there is still understandable reluctance to pursue such protocols because CNIs are considered such effective immunosuppressive agents, and organ replacement therapy analogous to dialysis is not available for other organ transplant recipients if severe rejection occurs. MMF has the advantage of being non-nephrotoxic. mTOR inhibitors have several disadvantages; they impair wound healing, potentiate the nephrotoxicity of cyclosporine, and sometimes induce proteinuria. Although some studies suggest that everolimus is better tolerated than sirolimus, similar nephrotoxic interactions have been reported between both sirolimus and everolimus with cyclosporine.[8] CNI-sparing strategies are discussed in more detail later.

Another strategy is to use tacrolimus as the *de novo* CNI or to switch from cyclosporine to tacrolimus if there is evidence of nephrotoxicity (cyclosporine is still commonly prescribed as the *de novo* CNI in heart and lung transplantation). The rationale here is that tacrolimus provides equivalent or even better immunosuppression at doses and concentrations that are less nephrotoxic than cyclosporine. Furthermore, tacrolimus is associated with less hypertension and hyperlipidemia (which might exacerbate CKD) than cyclosporine. Conversely, it is associated with more post-transplantation diabetes mellitus. Studies in nonrenal transplant recipients have yielded conflicting results as to which is more nephrotoxic.

The usefulness of calcium channel blockers in ameliorating CNI nephrotoxicity in renal transplantation remains controversial, and there is limited evidence of such benefit in nonrenal transplantation.

Changes in Measured Iothalamate GFR in Individual Patients after Lung Transplantation

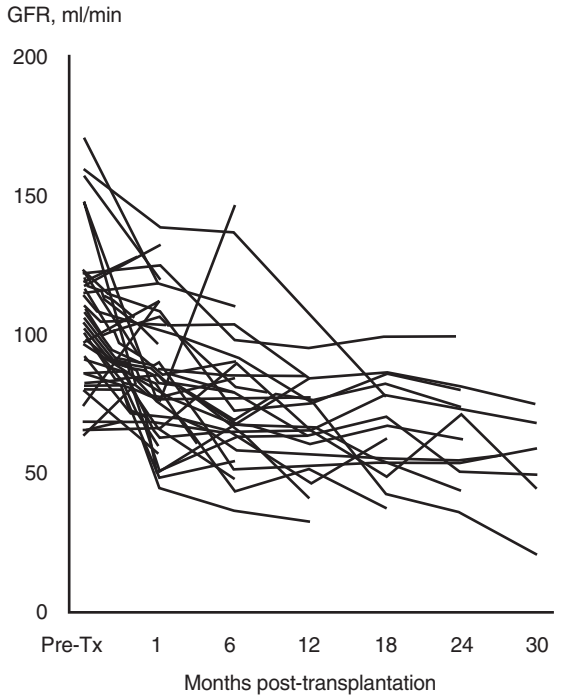

Figure 111-1 Changes in measured iothalamate glomerular filtration rate (GFR) in individual patients after lung transplantation. Note the variation in GFR before transplant and the large fall in GFR in many patients within the first 6 months. *Tx,* Transplantation. *(Adapted from reference 5.)*

Advantages and Disadvantages of Simultaneous Kidney and Other Solid Organ Transplantation

Advantages	Disadvantages
Potentially provides much better renal function over the short and long terms	Surgery more technically complex and prolonged Not needed when the AKI is reversible
Single donor—potential for lower cumulative dose of immunosuppression (as opposed to kidney transplantation later)	Deprives patients with "definite" ESRD of a kidney transplant

Table 111-1 Advantages and disadvantages of simultaneous renal and nonrenal transplantation. *AKI,* Acute kidney injury; *ESRD,* end-stage renal disease.

Causes of Acute Kidney Injury (AKI) After Solid Organ Transplantation

Prerenal	Intrarenal (ATN)	Postrenal
Hypovolemic shock (e.g., aggressive diuresis) Cardiogenic shock (e.g., severe cardiac allograft dysfunction) Distributive shock (e.g., sepsis) Cyclosporine or tacrolimus	Prolonged shock Cyclosporine or tacrolimus Aminoglycosides, amphotericin Intravenous contrast Hydroxyethyl starch, IVIG	Rare

Table 111-2 Causes of AKI after solid organ transplantation. *ATN,* Acute tubular necrosis; *IVIG,* intravenous immune globulin.

Experimental studies suggest that agents that block the renin-angiotensin system (RAS) may provide protection against the arteriolar hyalinosis and tubulointerstitial injury associated with chronic CNI use. Control of hypertension *per se* is probably more important than use of any particular antihypertensive agent.

Acute Kidney Injury in the Immediate Pretransplantation Period

It is not surprising that AKI can occur in the days to weeks immediately before liver, heart, or (less commonly) lung transplantation. Typically, the cause of AKI is either pre-renal (e.g., renal hypoperfusion or hepatorenal syndrome) or intrarenal (ischemic or toxic acute tubular necrosis) or a combination of both. AKI may develop on a background of CKD. A mildly elevated serum creatinine may mask a significant fall in GFR in malnourished patients with severe organ failure.[3] Reported rates of AKI vary widely; rates may be modified by varying definitions of AKI, organ-specific risks of AKI, and center variability in the type of patients listed for transplantation.

Management of AKI focuses on treatment of the underlying cause and provision of dialytic support according to standard criteria. Because the patients are critically ill, continuous renal replacement therapy (CRRT) may be preferred to intermittent hemodialysis, but there are no randomized controlled trials showing improved outcomes with this modality in this setting. When severe or prolonged AKI occurs before planned transplantation, estimation of the degree of reversibility becomes very important, because presumed irreversible severe kidney injury is generally a contraindication to transplantation or shifts the management toward simultaneous dual-organ (e.g., liver and kidney) transplantation. This is an area of ongoing debate in liver and, to a lesser extent, cardiac transplantation and is discussed in detail later. The general advantages and disadvantages of simultaneous dual-organ transplantation are shown in Table 111-1.

Although kidney biopsy might be useful in determining the degree of reversibility, in practice it is not commonly performed. This reflects the perceived technical difficulties of performing the procedure in critically ill—often coagulopathic—patients, in whom a biopsy-related bleed could have catastrophic consequences.

Acute Kidney Injury in the Early Post-transplantation Period

Acute kidney injury is also common in the days to weeks after transplantation. This reflects several factors: pretransplant renal function may have been compromised, the transplanted organ may have poor initial function, high doses of CNIs and other nephrotoxic agents may be prescribed, and the invasive surgery and high-dose immunosuppression predispose to severe infection (Table 111-2). AKI is associated with higher mortality in the early postoperative period.[9-11] This is likely to reflect both the association of AKI with other severe complications and also its direct effects on mortality. In those who survive, AKI is associated with an increased risk of developing CKD.[12]

Prevention or minimization of post-transplant AKI involves careful selection of patients for transplantation, meticulous perioperative care, and avoidance of nephrotoxic agents. Management of established AKI focuses on treatment of the underlying cause and

provision of dialytic support according to standard criteria. Intermittent hemodialysis and CRRT are both used. Delayed introduction or reduced doses of CNIs are sometimes used, usually under the cover of induction antibody immunosuppression. How much this strategy improves renal function remains unclear.

Chronic Kidney Disease

With the increasing number of solid organ transplants being performed worldwide and the longer survival of recipients, the absolute number of recipients with CKD has increased. In the largest and most comprehensive study to date, the cumulative incidence of post-transplant CKD (defined as estimated glomerular filtration rate [eGFR] <30 ml/min/1.73 m^2) at 5 years varied from 7% to 21% (Fig. 111-2).[12] By multivariate analysis, the following pretransplant variables increased the risk of development of CKD: increasing age, female gender, white or black (as opposed to Asian) ethnicity, lower GFR, diabetes mellitus, hypertension, hepatitis C virus infection, and need for dialysis. The following post-transplant variables were also implicated: postoperative AKI and initial use of cyclosporine (as opposed to tacrolimus).[12] These risk factors have been confirmed in other studies.

Many studies have also confirmed that whatever the transplanted organ, development of CKD, and especially of end-stage renal disease (ESRD), portends a poor prognosis (Fig. 111-3). Recipients with CKD have a relative risk of death of 4.6 compared with those without CKD.[12] The risk is highest in those with ESRD, but even in those not on dialysis, the relative risk of death was doubled.[12]

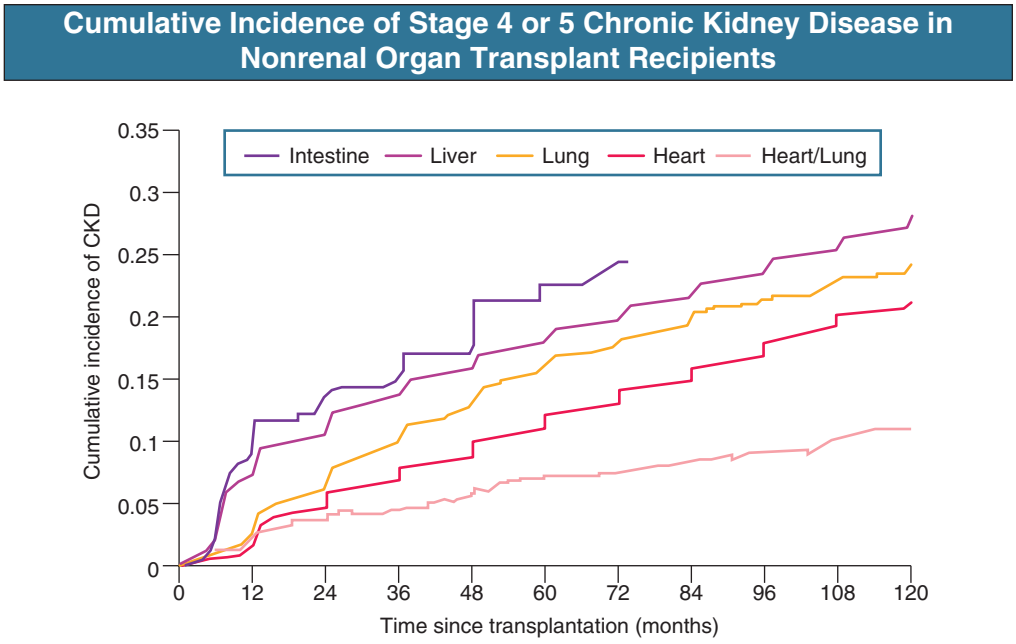

Figure 111-2 Cumulative incidence of CKD (eGFR <30 ml/min/1.73 m^2) after transplantation of various solid organs. *CKD,* Chronic kidney disease; *eGFR,* estimated glomerular filtration rate. *(Adapted from reference 12.)*

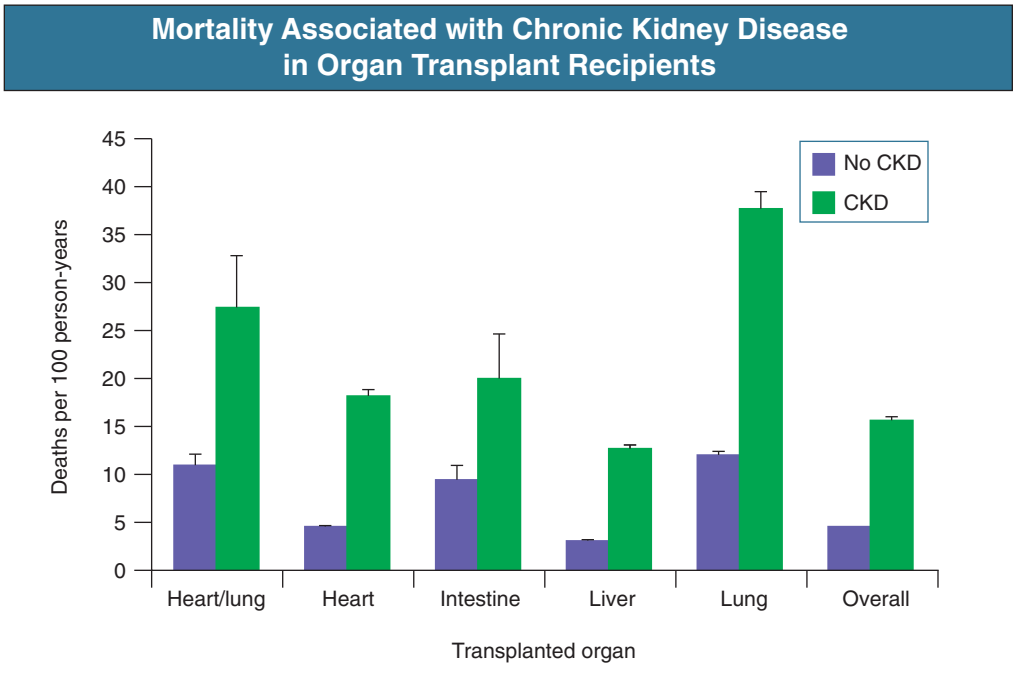

Figure 111-3 Mortality associated with stage 4 and 5 CKD in organ transplant recipients. *CKD,* Chronic kidney disease. *(Data from Scientific Registry of Transplant Recipients.)*

Although it has not been well studied, CKD in this setting is presumably associated with the same complications as in nontransplant recipients, including anemia, hypertension, fluid overload, and bone and mineral disorders. Indeed, these complications might be more severe in nonrenal transplant recipients because of other risk factors. For example, antiproliferative immunosuppressants exacerbate anemia and corticosteroids exacerbate metabolic bone disease.

Management of Chronic Kidney Disease

The MDRD equation (despite its limitations) is useful in identifying CKD in these patients. In all patients with rising serum creatinine or falling GFR, referral to a nephrologist should be considered. The initial evaluation should include thorough review of renal function in the peritransplantation period and exposure to nephrotoxins. If urinalysis shows moderate or severe proteinuria or hematuria or both, renal biopsy should be considered; it can be highly informative in identifying renal diseases other than CNI nephrotoxicity.[13]

Close consultation with the primary transplant team is important. When CNI toxicity is deemed the main cause of CKD (as it is in the majority of patients), reduction in CNI dosage for patients at low immunologic risk should be considered. To maintain adequate immunosuppression, if the patient is receiving azathioprine, a change to MMF should be considered; if the patient is already receiving MMF, the dose should probably be increased. An alternative strategy (one that I favor less) is to substitute an mTOR inhibitor for the CNI; this should not be done in the early post-transplant period because of the adverse effects of these drugs on wound healing. Finally, some have advocated switching of cyclosporine to low-dose tacrolimus, although the supporting data are less compelling. It should be noted that the majority of studies of CNI reduction or cessation in these settings are small, have limited follow-up, and are of limited quality.[14]

The general management of CKD has not been well studied in nonrenal transplant recipients, but it seems reasonable to use the same strategies used in the nontransplant CKD population. Thus, hypertension, anemia, and hyperparathyroidism should be managed according to standard guidelines. Although there is experimental evidence that angiotensin-converting enzyme (ACE) inhibitors might have important antifibrotic effects in nonrenal transplant CKD, there are no trials showing improved renal outcomes with ACE inhibitors or angiotensin receptor blockers compared with other antihypertensive agents. In practice, lifestyle modification and several antihypertensive drugs are usually required for achievement of target blood pressure.

In those with severe CKD, planning for renal replacement therapy including renal transplantation (where appropriate) should begin early. The majority are treated with hemodialysis rather than with peritoneal dialysis. With either modality, mortality is much higher compared with matched nontransplant controls.[15] Nevertheless, some have reported reasonable outcomes with home therapies (both hemodialysis and peritoneal dialysis).[16] Pending further studies, it seems that the choice of dialysis modality should be dictated by patient-specific factors.

There seems little doubt that in those fit for the procedure, sequential kidney transplantation is the best form of renal replacement therapy. Because patients have already undergone transplantation, the addition of the renal allograft does not imply a huge increase in immunosuppression (typically, this is increased only in the perioperative period). When it is feasible, a preemptive living donor transplant is probably the best option. Initial mortality is higher in nonrenal transplant recipients receiving a kidney transplant as opposed to staying on the waiting list (reflecting the complications of surgery and more immunosuppression), but mortality in the medium and long term is much lower.[12] The number of patients with a nonrenal transplant being wait-listed in the United States has increased significantly over the last 15 years.[15]

Prevention of Chronic Kidney Disease

The rate of development and progression of CKD can probably be reduced by minimizing post-transplantation AKI (see earlier) and by rigorous control of hypertension in the long term. Clearly, safe and effective non-CNI or low-dose CNI protocols would be an important advance in preventing severe CKD. Studies using induction antibody with corticosteroids, MMF, and low-dose tacrolimus are encouraging in this regard.[3,17]

BK Virus Nephropathy

BK virus nephropathy is a much-feared complication of kidney transplantation. Fortunately, although BK viruria is occasionally noted after liver, heart, or lung transplantation, the absolute risk of BK viremia and BK virus nephropathy remains low. This probably reflects the lack of a "second hit" to the native kidneys, such as human leukocyte antigen (HLA) mismatching or inflammation. Nevertheless, BK virus nephropathy should be considered in the differential diagnosis of "unexplained" renal dysfunction after solid organ transplantation, especially because more intensive maintenance immunosuppressive protocols involving combined MMF and tacrolimus are being increasingly used.

Acute Kidney Injury in the Late Post-transplantation Period

Severe AKI occasionally occurs late after transplantation. The major causes are shown in Table 111-2. Severe rhabdomyolysis has been reported, usually when statins are prescribed with cyclosporine and an inhibitor of the cytochrome P-450 system, such as diltiazem or ketoconazole and other azole-based antifungal agents. Treatment of late AKI is of the underlying cause plus the usual supportive measures.

KIDNEY DISEASE IN LIVER TRANSPLANTATION

Acute kidney injury is common before liver transplantation. Indeed, use of the MELD (Model for End-Stage Liver Disease) scoring system (which measures severity of hepatic dysfunction and risk of death) to guide allocation of deceased donor liver allografts means that a raised serum creatinine concentration increases the chances of the patient being offered a liver transplant.[18] The most common causes of AKI before transplantation are hepatorenal syndrome (see Chapter 76) and acute tubular necrosis or both. Prolonged hepatorenal syndrome may cause acute tubular necrosis. Glomerulonephritis (GN) is relatively common (cirrhosis is associated with IgA nephropathy, and hepatitis C with membranoproliferative glomerulonephritis [MPGN]) but is rarely the cause of severe pretransplantation kidney disease. If renal replacement therapy is required, CRRT is often preferred, in part because it is thought to have less effect than intermittent dialysis on intracranial pressure.

Post-transplantation AKI is also common and is usually multifactorial.[9] In one series, 37% of liver transplants were complicated by some degree of AKI, 19% necessitating renal replacement therapy.[9] Requirement for renal replacement therapy was associated with higher 30-day and 1-year mortality. Pretransplant AKI associated with hepatorenal syndrome often but not always improves if the transplant is successful.

Although relatively low doses of CNIs are traditionally used in liver transplantation (because rejection is less of a concern than in other solid organ transplants), CKD remains common and is associated with higher mortality.[12] Thus, although CNIs are an important cause of CKD, other factors must play a role. These include the high prevalence of hepatitis C and hepatitis B viral infections (which predispose to GN) and the high prevalence of diabetes mellitus. Protocols involving reduction or cessation of CNIs have shown promising results.[19] Delayed introduction of tacrolimus, with the cover of interleukin-2 receptor blockade, has been shown to better preserve renal function while maintaining excellent allograft and patient outcomes.[17] *De novo* use of sirolimus is not recommended because there is some concern that it may be associated with hepatic artery thrombosis; there are also concerns about using this drug in the later post-transplant period.

The number and percentage of simultaneous liver-kidney transplants have increased greatly in the United States in recent years. In 1998, for example, there were 98; in 2013, there were 494 (approximately 7.7% of total liver transplants).[20] The principal reason is that the MELD system heavily weighs higher serum creatinine concentration and prioritizes patients with renal dysfunction. Although patients with severe pretransplant kidney disease do benefit from a combined transplant procedure, there is concern that too many simultaneous liver-kidney transplants are being performed and that current practice is depriving "real" ESRD patients of deceased donor kidney transplants. The main issue, of course, is deciding which patients are likely to have meaningful renal recovery after liver transplant alone. Complicating factors in this setting are the known poor accuracy of serum creatinine (and equations based on it) in estimating GFR and concerns about the high risk of renal biopsy. Single-center studies suggest that use of a combination of clinical and histologic criteria allows effective prediction of which patients will benefit most from simultaneous liver-kidney transplantation.[21,22] These centers used iothalamate clearance to measure GFR in patients with suspected AKI. Renal biopsy was performed by the percutaneous or transjugular method and had a moderate rate of complications[21,22]; some believe that it adds little discriminating value.[3] A recent consensus conference has provided recommendations as to who should receive simultaneous liver-kidney transplants (Box 111-1).[18] These recommendations have been questioned, however.[23]

KIDNEY DISEASE IN CARDIAC TRANSPLANTATION

Preoperative AKI is common. In the largest reported study, 1% of heart transplant recipients required renal replacement therapy before transplantation.[12] The main cause of AKI is renal hypoperfusion from severe congestive heart failure. Ventricular assist devices are sometimes used as a bridge to cardiac transplantation and can improve renal function in this setting. It is interesting to note that there is emerging evidence that venous congestion is independently associated with the presence of AKI, although whether therapies based on reducing central venous pressure improve renal outcomes remains to be proven. In some patients there may also be a component of chronic kidney injury caused by renovascular disease or hypertension or atheroembolism.

Postoperative AKI is also common. In addition to the causes shown in Table 111-2, factors that may be important after cardiac transplant surgery are prolonged aortic cross-clamping, large fluid volume shifts, and prolonged allograft ventricular dysfunction. CKD is now well recognized as an important and common complication in the medium and long term (see Fig. 111-2). The cumulative incidence of stage 4 or stage 5 CKD in cardiac transplant recipients has been reported as 11% at 5 years, lower than in bowel, liver, or lung transplant recipients.[12] The principal cause of CKD after cardiac transplantation is CNI toxicity. Several studies have shown that early or late renal dysfunction is a risk factor for death after cardiac transplantation; furthermore, cardiac transplant recipients on dialysis have poorer survival compared with other ESRD patients.[24,25]

A number of studies have assessed reduction or cessation of CNIs in patients with significant CKD after cardiac transplantation. The majority are small and single-center studies and have shown improvement in GFR with no adverse effects on the allograft.[26,27] However, these studies are of patients at low immunologic risk and often do not have long-term follow-up. Indeed, one recent report warned of high rates of rejection after patients were switched to a corticosteroid plus MMF protocol.[28] Another pilot study showed concerning outcomes with a *de novo* CNI-free protocol,[29] which cannot at present be recommended.

As in liver transplantation, the question of whether the patient is best served by heart-alone or simultaneous heart and kidney transplantation sometimes arises. The concern here, again, is the reversibility of renal failure. The absolute number of such dual transplants remains low but is steadily increasing in the United States (71 in 2012, equivalent to about 3.3% of total heart transplants).[20] Some centers have reported good results.[30] However, one recent registry analysis found that simultaneous heart and kidney (as opposed to heart-alone) transplantation benefited only low-risk patients with eGFR below 33 ml/min.[31] Consensus guidelines have not yet been developed. At this time, it seems reasonable to limit the combined transplants to patients with at least a severity of kidney disease similar to that shown in Box 111-1.

Recommended Indications for Simultaneous Liver-Kidney Transplant in Patients Listed for Liver Transplant

- CKD with GFR 30 ml/min or lower
- AKI or HRS with creatinine 2 mg/dl (176 μmol/l) or more and dialysis for 8 weeks or longer
- CKD with biopsy showing more than 30% glomerulosclerosis or 30% interstitial fibrosis

Box 111-1 Recommended indications for simultaneous liver-kidney transplant in patients listed for liver transplant. *AKI,* Acute kidney injury; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate; *HRS,* hepatorenal syndrome. *(Adapted from reference 18.)*

KIDNEY DISEASE IN LUNG TRANSPLANTATION

Preoperative AKI is less common and severe, as evidenced by the fact that only 0.1% of lung transplant recipients are reported to require dialysis before transplantation.[12] CKD may be present before transplantation, however, because of diabetes mellitus or high exposure to aminoglycosides (mainly in patients with cystic fibrosis). AKI after lung transplantation is common; in one series, 56% of patients had at least a doubling of serum creatinine in the first 2 weeks after transplantation.[11] A recent analysis of United Network for Organ Sharing (UNOS) data showed that 5.5% of patients required renal replacement therapy after lung transplantation; short- and long-term survival in this group was dramatically lower.[32]

Acute kidney injury can occur for the usual reasons shown in Table 111-2, but a number of factors specific to lung transplantation

may be important. First, aggressive diuresis is often prescribed to minimize any pulmonary edema in the allograft.[11] Second, nephrotoxic antimicrobial agents, such as aminoglycosides and amphotericin, are sometimes required to treat resistant or severe infections.[11,33] Acute oxalate nephropathy leading to irreversible renal failure has been described in lung transplant recipients.[33] The pathogenesis is thought to involve gut hyperabsorption of oxalate because of impaired fatty acid absorption and altered gut flora. Although it is probably rare, this "new disease" emphasizes the importance of maintaining a broad differential diagnosis for any kidney disease occurring after solid organ transplantation and the usefulness of performing a renal biopsy when the clinical presentation is unusual.

As with other forms of post-transplantation CKD, the most common cause is probably CNI toxicity.[33] CNI dosages tend to be higher because of the increased risk of rejection in lung transplantation. A small number of studies have reported improvements in GFR when doses of CNIs were reduced, but more data are needed before this can be routinely recommended. If CNI reduction is attempted, it seems prudent to use MMF rather than mTOR inhibitors as additional immunosuppression in view of the risk of pneumonitis with the latter. *De novo* use of mTOR inhibitors is not recommended because they may cause breakdown of the bronchial anastomosis.

It is interesting to note that patients with pulmonary hypertension appear to have a lower GFR immediately before transplantation than do those with other diagnoses but have a less severe fall in GFR after transplantation.[5] This probably reflects the adverse effects of pulmonary hypertension on renal perfusion and reversal of these effects after successful lung transplantation. Simultaneous lung-kidney transplantation is rarely performed.[20]

KIDNEY DISEASE IN HEMATOPOIETIC CELL TRANSPLANTATION

The general purpose of hematopoietic cell transplantation (HCT) is to allow administration of otherwise lethal (and ideally curative) doses of chemoradiotherapy, followed by engraftment of stem or progenitor cells for marrow recovery.[34,35] Most commonly, HCT is used to treat hematologic cancers, but other indications now include certain nonhematologic cancers, severe genetic disorders (such as immunodeficiencies), and severe autoimmune diseases.[36] Stem and progenitor cells may be harvested from peripheral blood, bone marrow, or umbilical cord blood. Conventional myeloablative HCT uses intensive conditioning regimens involving high-dose chemotherapy and radiotherapy to ablate cancer cells and bone marrow; the hematopoietic system is then reconstituted by infusion and engraftment of stem cells. In allogeneic myeloablative HCT, nonself stem cells are used; in autologous myeloablative HCT, the patient's own cells are used. The toxicities of myeloablative regimens generally exclude older and sicker patients; nonmyeloablative or "reduced-conditioning" regimens have been developed to allow allogeneic HCT in such patients. In both forms of allogeneic HCT, acute and chronic graft-versus-host disease (GVHD) can be problematic; CNIs are typically prescribed to prevent and to treat this complication. The three main target organs of GVHD are the liver, gastrointestinal tract, and skin.

Tens of thousands of HCTs are performed worldwide every year.[36] It is now recognized that AKI and CKD are common complications of HCT and are associated with higher early and late mortality. The types of HCT and their associated renal complications are shown in Table 111-3.

Acute Kidney Injury After Hematopoietic Cell Transplantation

Acute kidney injury is common after HCT, but its incidence and severity depend on the type of HCT (and on the definition of AKI used in reported series). It is most common after myeloablative allogeneic HCT, reflecting the propensity of this regimen to cause profound immunosuppression (with associated risk of severe sepsis) and liver damage (with associated risk of hepatorenal syndrome; see later); furthermore, CNIs are routinely prescribed for the first 100 days after transplantation. Severe AKI is least common after nonmyeloablative HCT (even though patients are older and sometimes sicker), reflecting the shorter period of pancytopenia and rarity of sinusoidal obstructive disease of the liver as a post-transplant complication. The principal cause of AKI in this setting is probably CNI toxicity; severe AKI necessitating dialysis is relatively rare.[37]

Three Types of Hematopoietic Cell Transplantation (HCT) and Their Associated Renal Complications

	Myeloablative Allogeneic	Myeloablative Autologous	Nonmyeloablative Allogeneic
Diseases treated	Many leukemias, NHL, myelodysplastic syndromes	Lymphomas, multiple myeloma	As for myeloablative allogeneic type
Used in patients older than 60 years	Rarely	Sometimes	Common
Comorbidities permissible before HCT	Minimal	Minimal	Some
Intensity of conditioning regimen	High	High	Low
GVHD after HCT	Common	None	Common
CNIs used routinely	Yes	No	Yes
Incidence of AKI	Very common; sometimes severe	Common	Common; rarely severe
Causes of AKI	Hepatic sinusoidal obstruction syndrome, shock syndromes, nephrotoxic drugs, CNIs	Shock syndromes, nephrotoxic drugs; occasionally hepatic sinusoidal obstruction syndrome	CNIs
Incidence of CKD	Common	Common (but less severe than myeloablative allogeneic type)	Mild forms probably common
Causes of CKD	Irreversible AKI, renal TMA, CNIs, ?GVHD	Irreversible AKI	Pretransplant mild CKD, irreversible AKI, CNIs, ?GVHD

Table 111-3 The three types of hematopoietic cell transplantation and their associated renal complications. *AKI,* Acute kidney injury; *CKD,* chronic kidney disease; *CNIs,* calcineurin inhibitors; *GVHD,* graft-versus-host disease; *NHL,* non-Hodgkin lymphoma; *TMA,* thrombotic microangiopathy.

Causes of Kidney Disease According to Time After Hematopoietic Cell Transplantation

Immediate (Very Rare)	Early (AKI in First 3 Months)	Late
Tumor lysis syndrome	Prerenal	Thrombotic microangiopathy*
Marrow or stem cell infusion toxicity	Hypovolemia	CNI toxicity
	Hepatorenal syndrome	Irreversible AKI
	CNI toxicity	Membranous nephropathy or other glomerular diseases
	Intrarenal	Recurrence of original disease, which then affects kidneys (e.g., myeloma)*
	Ischemic and/or toxic ATN (shock syndromes, aminoglycosides, amphotericin, etc.)	?GVHD
	Postrenal	
	Hemorrhagic cystitis	

Table 111-4 Causes of kidney disease according to time after hematopoietic cell transplantation (HCT). *AKI,* Acute kidney injury; *ATN,* acute tubular necrosis; *CNI,* calcineurin inhibitor; *GVHD,* graft-versus-host disease. *Can cause late AKI also. *(Adapted from reference 37.)*

Myeloablative autologous HCT has an intermediate incidence of AKI. Whatever the form of HCT, if dialysis is required for severe AKI, the overall prognosis is usually very poor (early mortality >70%).[38,39] Fortunately, rates of AKI appear to be decreasing; this is probably related to multiple improvements in peritransplant care.[40]

It is helpful to consider the causes of AKI according to the time period after HCT (Table 111-4).[34] Within the first few weeks of myeloablative HCT, when the conditioning regimen has caused pancytopenia, mucositis of the gastrointestinal tract, and liver damage, recipients are at high risk of many forms of AKI. These include prerenal syndromes caused by hepatorenal syndrome (see later) and hypovolemia (induced by vomiting and diarrhea or bleeding). Neutropenia predisposes to septic shock. Exposure to nephrotoxic agents, such as amphotericin, aminoglycosides, intravenous contrast agents, and CNIs, is relatively common and may also precipitate acute tubular necrosis. Obstructive uropathy is much rarer but can be caused by severe hemorrhagic cystitis or fungal infection of the collecting system. Causes of hemorrhagic cystitis include high-dose cyclophosphamide and viral infection (by adenovirus or BK virus). BK virus nephropathy and adenovirus nephropathy have been described but appear to be rare.

Hepatic Sinusoidal Obstructive Syndrome

Hepatic sinusoidal obstructive syndrome (SOS) is also known as *veno-occlusive disease of the liver* and is one of the most common causes of severe AKI after myeloablative HCT, particularly allogeneic myeloablative HCT (see Tables 111-3 and 111-4). The pathophysiology is thought to involve radiotherapy- and chemotherapy-induced damage to the endothelium of hepatic venules with subsequent venular thrombosis and sinusoidal and portal hypertension. Risk factors for development of SOS include allogeneic HCT, older age, female gender, preexisting liver disease, use of cyclophosphamide or busulfan in the conditioning regimen, and exposure to methotrexate, progesterone, or antimicrobial drugs (i.e., infection).[38]

Clinically, SOS presents as a form of hepatorenal syndrome. Frequently there is a precipitating factor such as sepsis. SOS generally appears during the first 30 days after HCT. The initial symptoms and signs are weight gain, edema, and ascites, then right upper quadrant abdominal pain and tenderness, jaundice, and abnormal liver function test results. Falling urine output, low urine sodium, and rising serum creatinine then follow.[38,41] The severity of disease varies. In mild to moderate cases, sodium and fluid restriction, diuresis, and analgesia may be required, and the syndrome eventually resolves. Severe SOS complicated by liver and renal failure (and frequently respiratory failure) carries a mortality approaching 100%. The differential diagnosis includes acute GVHD of the liver, sepsis, drug-induced cholestasis, gallstone disease, and hepatotoxic effects of parenteral nutrition. The diagnosis of SOS is usually based on the typical clinical and laboratory features. On occasion, liver biopsy is needed to confirm the diagnosis.

Current preventive strategies for SOS include avoidance of precipitating factors when possible and use of ursodeoxycholate or low-dose heparin. Thrombolytics have been tested for treatment of severe VOD; it is not surprising that severe bleeding limits their use. The most encouraging therapy to date is defibrotide, an oligonucleotide with antithrombotic and fibrinolytic effects on microvascular endothelium, but with apparently few systemic adverse effects.[42] Defibrotide is also showing encouraging results as a preventive agent.[43]

Management of Acute Kidney Injury After Hematopoietic Cell Transplantation

Evaluation of the patient should be as for any patient with hospital-acquired AKI but with particular focus on the possible contribution of hepatorenal syndrome to the clinical picture. The patient's cancer diagnosis, conditioning regimen, and type of HCT should be carefully reviewed. When it is possible, further exposure to nephrotoxic drugs should be minimized (e.g., effective alternatives to amphotericin are now often available). If CNI trough concentrations are high, then reduction in dose should be considered. No randomized controlled trials have compared intermittent hemodialysis with CRRT in this setting. Whatever the modality used, the prognosis in those who develop severe AKI after HCT is poor. Continuous therapies do offer some potential advantages. In the setting of hepatorenal syndrome, there is some evidence that they are associated with less of an increase in intracranial pressure. In addition, the daily obligate fluid intake in these patients is frequently massive, and fluid balance is most easily controlled by a continuous technique. Vascular access can be problematic because of thrombocytopenia and neutropenia predisposing to bleeding and infection, respectively.

Chronic Kidney Disease After Hematopoietic Cell Transplantation

Chronic kidney disease is an important long-term complication of HCT, particularly allogeneic HCT.[35] Reported rates vary widely; in one review the cumulative incidence after HCT was 18% to 66%.[35] As recipients of HCT are living longer, CKD may become more prevalent, similar to the situation with solid organ transplants described earlier. GVHD is thought not to affect the kidneys directly. However, there is evidence that GVHD or its accompanying inflammatory state may cause glomerular disease (see later); some believe that it may play a role in the pathogenesis of CKD also.[35] The causes of CKD are shown in Table 111-4.

Thrombotic Microangiopathy

Subacute or chronic renal TMA is probably the most common cause of CKD (particularly severe CKD) after HCT,[44,45] although this has been disputed.[35] It typically first manifests 4 to 12 months after HCT. Characteristic clinical features are slowly rising serum creatinine, hypertension, and disproportionate anemia (see also Chapter 29). Dipstick urinalysis shows variable proteinuria and hematuria. Some patients have a much more fulminant presentation, however (e.g., as a severe nephritic syndrome). Careful review of previous laboratory test results will often show evidence of a low-grade TMA: intermittent or persistent elevation in plasma lactate dehydrogenase, low

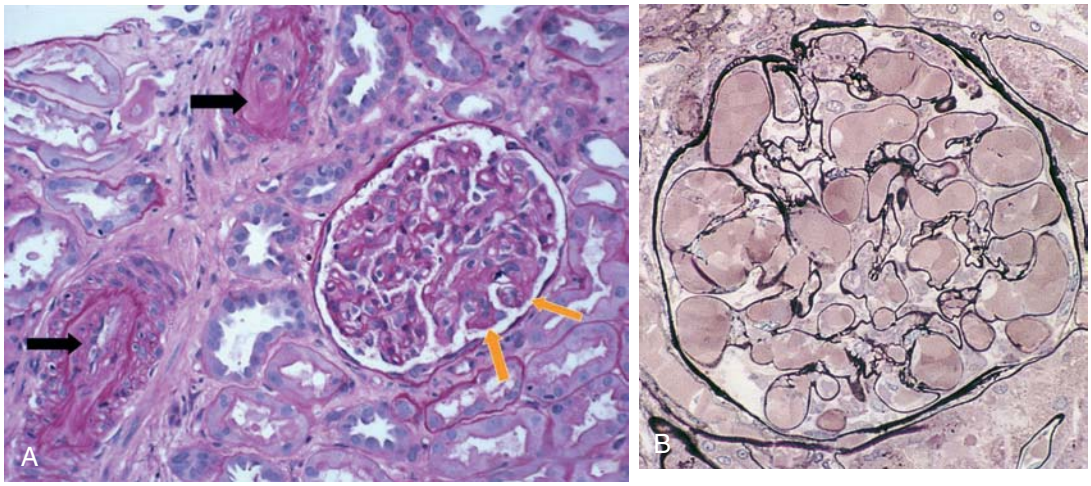

Figure 111-4 Thrombotic microangiopathy after allogeneic hematopoietic cell transplantation (HCT). A, Renal biopsy specimen from a patient who had undergone allogeneic HCT and developed subacute renal failure 12 months later. Periodic acid–Schiff (PAS) staining shows near occlusion of two small arteries by subintimal connective tissue and swollen endothelium *(black arrows).* The glomerulus shows thickened capillary walls with "double contours" and segmental occlusion and collapse of capillaries *(orange arrows).* **B,** Severe mesangiolysis in a patient with thrombotic microangiopathy (TMA) after HCT. Note the aneurysmal capillary loops and the lack of mesangial cells or matrix. *(**A** courtesy Dr. H. Rennke, Harvard Medical School, Boston, Massachusetts.)*

serum haptoglobin, low platelets, low hemoglobin, and sometimes schistocytosis. A summary of diagnostic criteria (and their limitations) is provided in reference 45. It should be noted that the classic laboratory findings of TMA may not all be present (or have been recorded).[44] Renal imaging is usually unremarkable. Kidney biopsy is rarely required unless the presentation is atypical, because the biopsy findings are unlikely to significantly alter management and the biopsy carries increased risks in patients with thrombocytopenia and other morbidities. Histopathology typically shows microthrombi in arterioles and glomerular capillaries, mesangiolysis, glomerular basement membrane duplication, and tubular injury with interstitial fibrosis (Fig. 111-4).[44] The main cause of TMA after HCT is thought to be direct damage to the renal endothelium, and possibly the tubulointerstitium, by the chemoradiotherapy conditioning regimen (particularly the radiotherapy component).[45] Renal tissue has much slower turnover than mucosal cells do and thus manifests chemoradiotherapy damage much later. Other factors, such as infection, GVHD, CNIs, and activation of the RAS, may play a facilitating role (Fig. 111-5).[34,45] Deficiency of ADAMTS13 is thought not to be the primary cause in most patients.[45] Treatment of renal TMA after HCT is mainly supportive (see later). Prevention involves renal shielding (from irradiation damage) and avoidance of other nephrotoxic agents at the time of conditioning.

Calcineurin Inhibitor and Sirolimus Nephrotoxicity

Calcineurin inhibitors are routinely prescribed after allogeneic HCT to prevent and to treat GVHD. Long-term use of CNIs very likely contributes to CKD, as described earlier for solid organ transplantation. However, as CNIs are often stopped after 3 to 6 months (unless there is ongoing GVHD), their contribution to CKD is generally thought to be limited. The contribution of CNIs to chronic renal TMA is unclear. TMA can certainly occur in patients on non-CNI protocols.[46] There is a high incidence of TMA when sirolimus is added to CNI therapy, but fortunately this is often reversible.[47]

Glomerular Disease

Nephrotic syndrome has been described after both allogeneic and autologous HCT. In allogeneic HCT, it appears to be strongly associated with the presence of GVHD and to respond to more immunosuppression. *De novo* membranous nephropathy is the most common biopsy finding; minimal change disease has also been reported.[48] The original hematologic disease (such as myeloma) may also recur with renal involvement.

Management of Hematopoietic Cell Transplantation–Related Chronic Kidney Disease

Careful review of the patient's pre- and post-HCT history is essential. Attention should be paid to the following: type of HCT and conditioning regimen (in particular, whether total body irradiation was used and at what dose) and degree of exposure to nephrotoxins. The examination frequently shows hypertension, hypervolemia, and skin GVHD. Blood test results should be reviewed carefully and tests repeated to assess for TMA; the laboratory features of TMA are often intermittent and not florid. Urine dipstick findings of hematuria and moderate proteinuria are suggestive of renal TMA but of course are not specific to this condition. Renal ultrasound is often used to exclude post-renal causes, but other imaging studies are usually unnecessary. As discussed before, kidney biopsy is rarely indicated.

General treatment should be as recommended for any patient with CKD. Aggressive control of hypertension is warranted. For the patient with TMA, plasma exchange does not appear to be beneficial.[49] There is only limited evidence in this setting of the superiority of drugs that block the RAS system, but their use seems reasonable.[50] CNI doses should probably be minimized if this is thought "safe" for the management of the HCT. Substitution of CNIs with interleukin-2 receptor blockers in the setting of GVHD and renal dysfunction might improve renal function but remains experimental at this time.[51] A subset of patients will progress to ESRD, and overall these patients have worse survival on dialysis than non-HCT controls do.[46] Suitability for renal transplantation should be judged carefully on a case-by-case basis. On occasion, the allogeneic stem cell donor can donate a kidney; a great benefit of this approach is that a state of tolerance to the allograft should exist, and hence minimal or no immunosuppression is required.[52] If this option is not available and the patient receives a conventional kidney transplant, low-dose immunosuppression should generally be prescribed because HCT recipients may not have normal immunity and remain at higher risk of infection. Good outcomes after renal transplantation have been reported in carefully selected patients.[52,53]

pathological features of, 218, 225
treatment of, 228
Secondary hypertension
evaluation for, 403-404, 404t-405t
hypertensive emergency evaluation and, 441
Secondary membranous nephropathy
diagnosis for, 245
histopathologic features of, 242-243, 243t
light microscopy and, 242
Secondary minimal change disease, 216-217
Secretory defect, hypokalemic distal renal tubular acidosis (type 1) and, 152
Secretory IgA, 266
Segmental glomerulus injury, 198
Seizure, as dialysis complication, 1087, 1088f
Seldinger technique, 1058-1061
Selective serotonin reuptake inhibitor, 901
Seminal vesicle cyst, 543
Senior-Loken syndrome, 554
Sensitization, 1219
Sensory polyneuropathy, 363, 364f
Sepsis, acute kidney injury in pregnancy and, 519
Sericin, 1016
Serum amyloid P component, 317
Serum calcium, 987
Serum creatinine
acute kidney injury definition and, 827
chronic allograft injury and, 1219
estimated glomerular filtration rate and, 33-35, 33t, 931, 933
incidence of acute kidney injury and, 836, 837b, 837f
measurement of, 369
natural progression of kidney disease diagnosis and, 932b
for transplant recipient glomerular filtration rate estimation, 1257
Serum cystatin C, 34b, 36-37
Serum electrolyte, chronic kidney disease during pregnancy and, 525
Serum homocysteine, 1013
Serum phosphorous, progression of kidney disease and, 939
Serum potassium, 111
Serum protein, low-molecular-weight, 37
Serum sodium concentration, 96
Serum urea, as glomerular filtration rate index, 32t
Shiga toxin-producing *Escherichia coli*-associated hemolytic uremic syndrome
clinical course of, 342-343, 342f
diagnosis of, 342
mechanisms of, 341-342
pathology of, 340-341, 341f
therapy for, 343, 344t
Short consensus repeat domain, 261-262
Shunt nephritis, 669-670
Sibling vesicoureteral reflux, 740
Sickle cell anemia, 108
Sickle cell disease
clinical manifestations of, 601-603, 603f
definition of, 601
epidemiology of, 601-604
natural history of, 603, 603f
pathogenesis of, 601
genetics and, 601
pathophysiology of, 601, 602f
treatment of, 604
Sickle cell nephropathy
age-dependent pattern of, 606-611, 607t
chronic kidney disease as, 609-611
definition for, 601
hypertension as, 609
pathogenesis of
concentrating capacity and, 604-605, 604f-605f
diluting capacity and, 605
glomerular injury and, 605-606
hormones in, 606
other tubular abnormalities and, 605
renal hemodynamics and, 605
proteinuria and nephrotic syndrome as, 608-609
sodium and acid-base disturbances as, 609
transplantation and, 611
urinary tract infection as, 608
Sickle cell trait, 601
Sickling
hematuria and, 607
sickle cell disease and, 601, 602f
Silent lupus nephritis, 308-309
Simon, John, 1024
Simple cyst (renal)
clinical manifestations of, 561
definition of, 561
diagnosis of, 561-562
etiology and pathogenesis of, 561
pathology of, 561
treatment of, 562
ultrasound and, 53
Simple diffusion, 17
Simultaneous pancreas-kidney transplant, 1243, 1244f
Single-nephron glomerular filtration rate (SNGFR), 14
Single-photon emission computed tomography (SPECT), 59
Single-pool *Kt/V*, 1078, 1078t
Sirolimus
chronic kidney disease and nephrotoxicity of, 1264
drug-related gastrointestinal complications and, 1195
focal segmental glomerulosclerosis and, 228
hypokalemia and, 1208-1209
mTOR and, 1148-1149
post-transplant lymphoproliferative disorder and, 1198-1200
Sjögren syndrome
acute interstitial nephritis and, 735
chronic interstitial nephritis and
clinical manifestations of, 754
definition and epidemiology of, 754
pathology of, 754
treatment of, 754
hypokalemic distal renal tubular acidosis (type 1) and, 152
Skeletal defect, nail-patella syndrome and, 576, 577f
Skeleton
calcium fluxes and, 124, 126f-127f
radiology of, 988, 989f
Skin
cancer of
post-transplant neoplasms and, 1196-1197
post-transplant recipient and, 1199
Fabry disease manifestation as, 575, 575f
hyperparathyroidism and, 987
Skin emollient, uremic pruritus treatment and, 1016
Skin lesion, cutaneous aging and, 1015
Skinfold thickness, 1011f
Slit diaphragm. *See also* Filtration barrier, glomerular

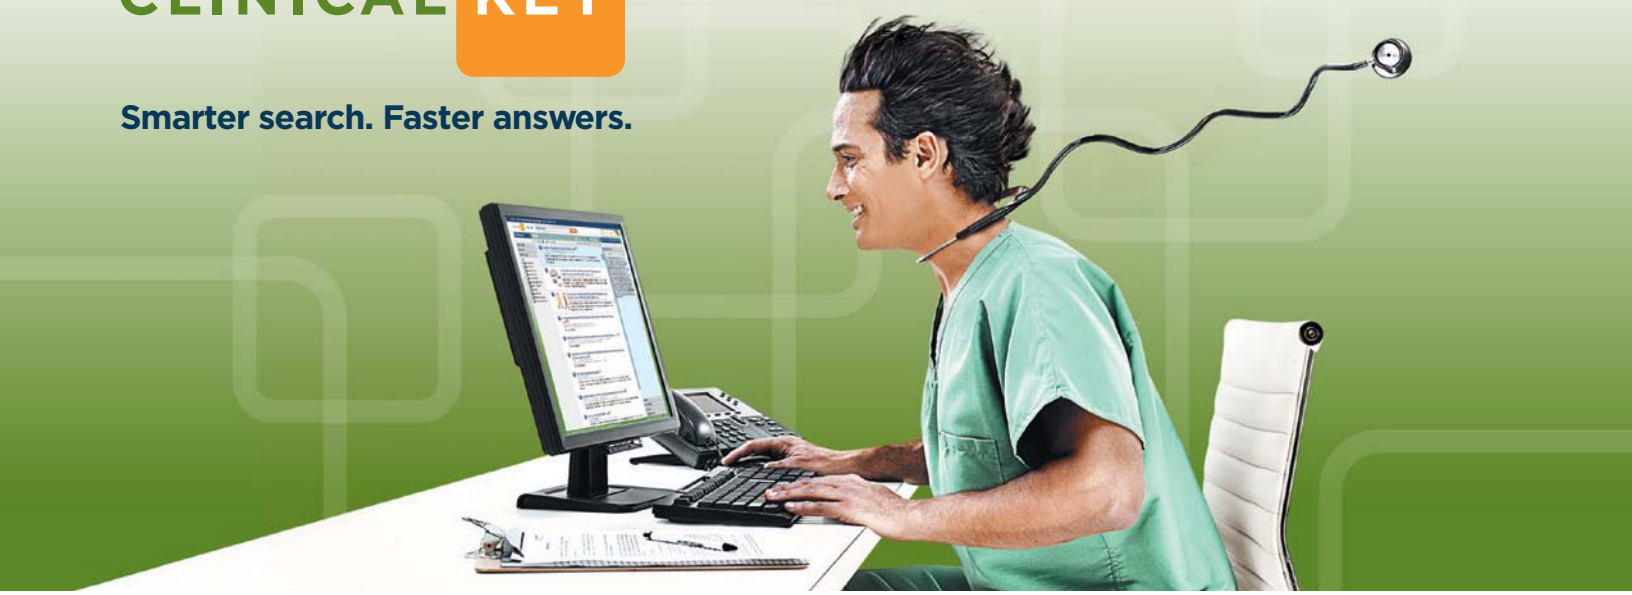
CLINICAL KEY™

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.

ELSEVIER
